We study a quantum phase transition from a massless to massive Dirac fermion phase in a new two-dimensional bipartite lattice model of electrons that is amenable to sign-free quantum Monte Carlo simulations. Importantly, interactions in our model are not only invariant under SU(2) symmetries of spin and charge like the Hubbard model, but they also preserve an Ising like electron spin-charge flip symmetry. From unbiased fermion bag Monte Carlo simulations with up to 2304 sites, we show that the massive fermion phase spontaneously breaks this Ising symmetry, picking either anti-ferromagnetism or superconductivity and that the transition at which both orders are simultaneously quantum critical, belongs to a new “chiral spin-charge symmetric” universality class. We explain our observations using effective potential and renormalization group calculations within the framework of a continuum field theory.

The study of graphene has triggered an avalanche of interest in the physics of massless relativistic fermions in two spatial dimensions, highlighting the connections between condensed matter and high energy physics theory, and the unity of physics across disparate energy scales [1–5]. While the simplest models of graphene result in massless Dirac fermions, a basic question that has been scrutinized heavily is how and when these low energy excitations can develop a mass gap [6–8]. Of particular interest in this work is the situation when strong energy excitations can develop a mass gap [6–8]. Of particular interest in this work is the situation when strong electron-electron interaction drives the mass generation. The most common mechanism is through spontaneous symmetry breaking in which the order parameter couples to a mass term in the Dirac equation. Examples include the formation of Néel order [9, 10] or a valence bond solid [11, 12].Typically the critical point between the massless Dirac phase and the symmetry broken state is described by some Gross-Neveu-Yukawa (GNY) field theory [13], see however [14–16].

The simplest route to the two-dimensional massless Dirac equation on a lattice, is through the hopping of electrons,

\[ H_0 = -\sum_{\langle i,j \rangle \alpha} t_{ij}(c^\dagger_{i\alpha}c_{j\alpha} + c^\dagger_{j\alpha}c_{i\alpha}), \]

with an appropriately chosen \( t_{ij} \), where \( c_{i\alpha} \) destroys an electron on lattice site \( i \) with spin \( \alpha = \uparrow, \downarrow \). In this work we study the hopping matrix elements \( t_{ij} \) with a two-dimensional bipartite structure that preserves particle-hole symmetry and is independent of the electron spins. At low energies the electronic spectrum of such a model is described by spin degenerate (\( N_f = 2 \)) four-component massless Dirac fermions. The most celebrated example of such a model is nearest neighbor hopping on a honeycomb lattice with \( t_{ij} = t \), which is a basic model for the electronic structure of graphene [1]. Another popular example is a square lattice with nearest neighbor hoppings \( t_{ij} = t \eta_{ij} \) where the phases \( \eta_{ij} \) realize a \( \pi \)-flux on each fundamental plaquette [17]. To obtain a \( \pi \)-flux on a square lattice we can choose \( \eta_{i,i+e_y} = 1 \) and \( \eta_{i,i+e_x} = (-1)^i \), where \( e_x \) and \( e_y \) are the unit vectors in the \( x \) and \( y \) direction, and \( i_x \) is the \( x \) component of \( i \).

In addition to the usual lattice symmetries and time reversal, \( H_0 \) possesses certain internal symmetries which will play a central role in our work. Most well-known is the SU(2)\( _s \) spin rotational symmetry which is generated by \( \vec{S}^s_i = \frac{1}{2}(c^\dagger_{i\uparrow}c_{i\downarrow} + c^\dagger_{i\downarrow}c_{i\uparrow}) \), charge symmetry [18], which is generated by \( \vec{C}^c_i = \frac{1}{2}(\vec{c}^\dagger_{i\uparrow} \vec{c}^\dagger_{i\downarrow} + \vec{c}^\dagger_{i\downarrow} \vec{c}^\dagger_{i\uparrow}) \), where \( \vec{c}^\dagger_{i\alpha} \rightarrow \vec{c}^\dagger_{i\alpha}, \vec{c}_{i\alpha} \rightarrow \vec{c}_{i\alpha} \), and the generators of spin and charge rotations are interchanged, \( \vec{S}^c_i \leftrightarrow \vec{C}^s_i \). The SU(2)\( _s \) × SU(2)\( _c \) symmetries can be combined into an O(4) symmetry [19]. This O(4) symmetry is most manifest when the hopping Hamiltonian is rewritten in terms of real “Majorana” modes \( \gamma^a_i \), with \( a = 1, 2, 3, 4 \), and \( \gamma^a_i \) transforming in the vector representation of O(4), the hopping taking the form, \( H_0 = \sum_{\langle i,j \rangle \alpha \beta} \frac{t_{ij}}{2}(\gamma^a_i \gamma^{a^\dagger}_j - \gamma^{a^\dagger}_i \gamma^a_j) \).

Most often electron-electron interactions are added to Eq. (1) by the Hubbard-\( U \) term, \( H_U = U \sum_i (n_{i\uparrow} - \frac{1}{2})(n_{i\downarrow} + \frac{1}{2}) \). This term preserves the SU(2)\( _s \) and SU(2)\( _c \) symmetries but being odd under the \( \mathbb{Z}^sc \) acts like an Ising magnetic field that breaks the spin-charge flip symmetry. It is well known that repulsive-\( U \) interactions favor an antiferromagnetic (AFM) “spin” order parameter \( \vec{S}^s \), and attractive-\( U \) favors a combined charge-density wave (CDW)/superconducting “charge” order parameter \( \vec{C}^c \). We can understand how these orders couple to the fermions in a simple mean-field model, \( H_{\text{MF}} = H_0 + \sum_i \gamma^a_i (\vec{S}^s_i \cdot \vec{S}^s_i + \vec{C}^c_i \cdot \vec{C}^c_i) \). For \( U > 0 \), \( \vec{S}^s \neq 0 \) but \( \vec{C}^c = 0 \) (and vice versa for \( U < 0 \)). Since \( H_0 \) realizes a 2+1 dimensional Dirac dispersion, long range order sets in at a finite-|\( U \)| phase transition which is described by the so-called “chiral-Heisenberg” GNY fixed point that has been subject of intense numerical [20–23] and
field theoretic studies [24–27]. In this work we look into the nature of the quantum critical phenomena when we add electron-electron interactions to Eq. (1) that preserve the full O(4) symmetry of the hopping problem, including the crucial $Z_2^L$ symmetry, which is absent in the usual Hubbard formulation.

Clearly the full O(4) symmetry of Eq. (1) will be preserved if we add interactions that depend only on $\sum_{\alpha=1,\pm}(c^\dagger_{i\alpha}c_{j\alpha} + c^\dagger_{j\alpha}c_{i\alpha})$ with $i, j$ on opposite sublattices. To this end we focus on a sign-problem-free “designer Hamiltonian” (in natural units) which satisfies this criterion,

$$H_{SC} = -\sum_{\langle i,j \rangle}\exp\left(\kappa\eta_{ij}\sum_{\alpha=1,\pm}(c^\dagger_{i\alpha}c_{j\alpha} + c^\dagger_{j\alpha}c_{i\alpha})\right).$$

Our model may be viewed as an interacting Hubbard-like model (identical Hilbert space) but with spin-charge flip symmetry present. Note that our model can be written as a sum of terms defined on bonds of the lattice that consist of fermion bilinears and 4-, 6- and 8-fermion interactions (but no higher order terms) [19]. For $\kappa \ll 1$ the fermion bilinear terms reproduce Eq. (1) with $\tilde{t}_{ij} = \kappa\eta_{ij}$, and since fermion interactions are perturbatively irrelevant at the massless fixed point the semi-metal phase must emerge at $\kappa \ll 1$. For $\kappa \gg 1$, we show using numerical simulations that the Dirac fermions acquire a mass, but because of the spin-charge flip symmetry both $\phi^c$ and $\phi^\xi$ are degenerate and the system breaks the $Z_2^L$ symmetry by picking one of the two ground states. We present numerical evidence below that the phase transition between Dirac semi-metal and spin-charge flip broken phase is continuous and in a new universality in which both order parameters are simultaneously quantum critical. We note that other models preserving the spin-charge flip symmetry include a four-fermion model [19, 28] and various fermion-boson models [29, 30], although they do not harbor the new critical point.

Our designer Hamiltonian Eq. (2) was chosen because we can adapt a fermion bag QMC algorithm to study it [31, 32]. By renormalization group (RG) arguments, Eq. (2) is expected to capture universal aspects of the new quantum critical point [33]. The fermion bag algorithm is applicable to all Hamiltonians that are made up of only local terms whose fermionic degrees of freedom are exponentiated bilinears. While this is a limited family of systems, the algorithm is very efficient within its scope of applicability [31]. We expand the partition function $Z = \text{Tr} e^{-H_{SC}/T}$ as $Z = \sum_k \int [d\tau] \left(\begin{array}{c} \cdots \\
\end{array}\right) H_{SC}(\tau_k) \cdots H_{SC}(\tau_2) H_{SC}(\tau_1)$. Here the notation $\int [d\tau]$ denotes time-ordered integration for times $1/T \geq \tau_k \geq \cdots \geq \tau_2 \geq \tau_1 \geq 0$. The expansion can be derived from the continuous-time interaction representation where $H_0 = 0$ and $H_{int} = H_{SC}$ [34–39], and also resembles the stochastic series expansion [40, 41]. The algorithm then involves exploring a configuration space made up of the terms in the expansion, and makes use of locality to compute transition probabilities as small determinants [31, 32]. With two spin species, it is immediately evident that there is no sign problem in the expansion, because every term in the sum is the square of a real number. However, we note that even in models of the form Eq. (2) but with an odd number of flavors there is still no sign problem [42–45]. We compute two correlation functions of order parameters,

$$C_S = 2\langle S_{i_0}^z S_{i_1}^z \rangle, \quad C_U = \langle U_{i_0}^z U_{i_1}^z \rangle,$$

where $C_S$ measures the Néel order through the anti-ferromagnetic spin order parameter $S_i^z$ and $C_U$ measures the breaking of the spin-charge symmetry through the order parameter $U_i = (n_{i\uparrow} - \frac{1}{2})(n_{i\downarrow} - \frac{1}{2})$, which is a four-fermion operator that is odd under $Z_2^L$, but invariant under $\text{SU}(2)_s \times \text{SU}(2)_c$. In Eq. (3) $i_0 = (0, 0)$ and $i_1 = (L/2, 0)$ and we assume $L/2$ is even. We work at a finite inverse temperature $1/T = L$ and for numerical convenience we henceforth work with the tuning parameter $g = 2\tanh \frac{\eta}{2}$ instead of $\kappa$ [19].

We first investigate the nature of the massive phase in our lattice model, $H_{SC}$, using the QMC method described above. We work at a coupling $g = 1.6$, which is deep in the massless phase. As shown in Fig. 1, we find a finite value of $C_U$ in the thermodynamic limit, which indicates that the Ising symmetry, $Z_2^L$, is spontaneously broken. Further we find that $C_S$ also scales to a finite value in the thermodynamic limit, which implies Néel order. Together we interpret this to imply that the system has to spontaneously choose between the charge and the spin sector, breaking $Z_2^L$, and forming either a Néel state, or a superconductor/CDW state which breaks the corresponding $\text{SU}(2)$ symmetry. Next, using QMC we study the nature of the phase transition between the Dirac semi-metal and the massive phase. Fig. 2 shows the data for $C_S$ as a function of system size $L$. For large values of $L$, there is clear evidence that $C_S$ converges to a non-zero constant at the coupling $g = 1.6$ (massive phase), while it scales to zero at the coupling $g = 1.48$ (Dirac semi-metal). A good fit to the power-law $C_s = 0.67/L^{2.25}$ for $12 \leq L \leq 48$ with a $\chi^2 = 0.95$ is found at the coupling $g = 1.52$ as expected at a quantum critical point. A multi-parameter scaling fit of all our data except for $L = 12$, to the form $C_S = L^{-\nu}f(|(g - g_c)|L^{1/\nu})$ with $f(x) = f_0 + f_1 x + f_2 x^2 + f_3 x^3$ yields $\eta = 1.38(6)$, $\nu = 0.78(7)$, $g_c = 1.514(8)$, $f_0 = 0.96(15)$, $f_1 = 0.073(26)$, $f_2 = 0.0012(43)$, $f_3 = 0.0026(32)$ with a $\chi^2 = 1.25$. Interestingly, the large value of $\eta$ clearly establishes that this criticality is not captured by the chiral-Heisenberg theory. We note that $\eta > 1$ although uncommon has been observed at certain critical points previously [26, 46, 47]. In the inset of Fig. 2 we show the scaling collapse of this data using the functional form of the multi-parameter fit, providing strong evidence for a continuous quantum critical point.

To capture this observed phenomena, we formulate a
field theory in the Euclidean space-time Lagrangian picture [19] in terms of the continuum fields that are expected to appear as long distance fluctuations near the critical point. These are 8-component fermion fields $\bar{\psi}, \psi$ which are acted upon by tensor products of $4 \times 4$ Dirac matrices $\gamma^\mu$ and a spin Pauli matrix $\vec{\sigma}$. In terms of these fields, the spin and charge order parameter densities are given by $\vec{M}_s = \bar{\psi}_0 \vec{\sigma} \gamma^0 \psi_1 + \bar{\psi}_1 \gamma^0 \psi_0 + i(\bar{\psi}_1 \gamma^0 \psi_1 - \bar{\psi}_0 \gamma^0 \psi_0)$, and $\vec{M}_c = \bar{\psi}_0 \vec{\sigma}_2 \gamma^2 \psi_1 + \bar{\psi}_1 \vec{\sigma}_2 \gamma^2 \psi_0$. Then we can write down the following Yukawa like Lagrangian density,

$$\mathcal{L}_Y = -\bar{\psi}_a \gamma^\mu \partial_\mu \psi_a + g_s \bar{\phi}_s \cdot \vec{M}_s + g_c \bar{\phi}_c \cdot \vec{M}_c,$$

where the first term is the free Dirac theory and the second term describes the interactions of the fermionic fields with critical bosonic fields $\bar{\phi}_s$ and $\bar{\phi}_c$ that describe the fluctuations of the anti-ferromagnetic and CDW/superconducting order parameters. In addition to these terms involving the fermionic fields, we supplement our theory with the kinetic terms and self-interactions of the bosonic fields,

$$\mathcal{L}_B = \sum_{a=s,c} \left( \frac{1}{2} \partial_\mu \phi_a \partial^\mu \phi_a + \frac{1}{2} m_{sc}^2 \phi_a \cdot \phi_a + \frac{1}{4!} \lambda_{a} (\phi_a \cdot \phi_a)^2 \right) + \frac{1}{12} \lambda_{ac} (\phi_s \cdot \phi_c)(\phi_c \cdot \phi_c).$$

The first line in the above equation is the usual O(3) $\phi^4$ model for spin and charge sectors. The second line describes a quartic interaction between the spin and charge bosonic fields that is allowed by symmetry. Previous studies of multi-component field theories with fermions have not considered the above model [48-52].

The Euclidean Lagrangian density $\mathcal{L}_Y + \mathcal{L}_B$ is expected to describe the critical phenomena in our model. This theory is symmetric under SU(2)$_s$ and SU(2)$_c$: to impose the $\mathbb{Z}_2^c$ we need to require in addition $g_s = g_c$, $\lambda_s = \lambda_c$, and $m_{sc} = m_c$. Then this continuum theory possesses the full O(4) symmetry of our lattice Hamiltonian, and a thorough analysis of all the Yukawa couplings that are allowed by this O(4) symmetry can be found in [53]. When $m_{s,c}$ are large, the bosons will be gapped
and we expect a fixed point with massless Dirac particles which we identify with the semi-metal phase in our lattice model. As $m_{s,c}$ is lowered we expect the bosons to condense resulting in a massive phase. Interestingly in this phase the Dirac fermions mediate an interaction between the $\phi_{s,c}$ order parameters. To obtain the effective potential, we assume the condensed bosonic fields are constant in space-time, then we use the O(3) symmetry to rotate $\phi_{s,c}$ fields so they point in the $z$-direction. In this basis, the $\uparrow$ electrons feel a mass $\phi^+ = \phi_s^+ + \phi_c^+$ and $\downarrow$ electrons experience $\phi^- = \phi_s^- - \phi_c^-$. Integrating out the fermions creates an identical effective potential for $\phi^\pm$, which means in the massive phase $\phi^\pm$ condense to the same magnitude but differ at most by a sign (that is determined spontaneously). In the $\phi_{s,c}$ language this implies that in the massive phase in the presence of $Z_2^c$, the system spontaneously chooses to condense one of $\phi_{s,c}$ and leave the other uncondensed. This is a remarkable mechanism of repulsion between the $\phi_s$ and $\phi_c$ that is generated by the interaction with fermions. The result of an explicit calculation [19] of the effective potential from the fermion determinant is plotted in the inset of Fig. 1, confirming the nature of the massive phase. If $g_s \neq g_c$, the Ising symmetry would be broken and the minima would not be degenerate and the system would then favor the spin (charge) sector as happens in the repulsive (attractive) Hubbard model.

Since all the non-linear couplings $\lambda_s, \lambda_c, \lambda_{sc}, g_s, g_c$ become marginal in four dimensions, we can study the critical region of $\mathcal{L}_Y + \mathcal{L}_B$ using the perturbative RG in $4 - \varepsilon$ dimensions. We have obtained identical one-loop flow equations using both dimension regularization with minimal subtraction [54] and a soft cutoff method [55] for the massless theory [19],

$$\frac{d g_s^2}{d \log \ell} = \varepsilon g_s^2 - \frac{1}{8\pi^2} \left( 2N_f + 1 \right) g_s^4 + 9g_s^2g_c^2,$$

$$\frac{d \lambda_s}{d \log \ell} = \varepsilon \lambda_s - \frac{1}{8\pi^2} \left( \frac{11}{6} \lambda_s^2 + \frac{1}{2} \lambda_{sc}^2 + 4N_fg_s^2 \lambda_s - 24N fg_s^4 \right),$$

$$\frac{d \lambda_{sc}}{d \log \ell} = \varepsilon \lambda_{sc} - \frac{1}{8\pi^2} \left( \frac{5}{6} (\lambda_s + \lambda_c) \lambda_{sc} + \frac{2}{3} \lambda_{sc}^2 \right) + 2N_f(g_s^2 + g_c^2) \lambda_{sc} - 24N_f g_s^2 g_c^2. \tag{6}$$

The flow equations for $g_c^2$ and $\lambda_c$ are obtained by exchanging the $s$ and $c$ subscripts using spin-charge flip symmetry. We now study the fixed points of these flow equations. We note that we can choose $N_f$ in different ways: in $2 + 1d$ our case of interest $N_f = 2$, on the other hand our lattice model when extended to $3 + 1d$ would give $N_f = 4$. An $\varepsilon$ expansion with either choice can be formulated, and does not affect our main conclusions except for quantitative estimates for the critical exponents. We proceed with $N_f = 2$. Since the $g_{s,c}$ equation does not involve the quartic boson interactions, we can solve them separately. The Yukawa flow equations have four zeros in $(g_s, g_c)$: $(0, 0)$ is the unstable Gaussian fixed point (G), $(\frac{4}{5}\pi^2 \varepsilon, \frac{4}{5}\pi^2 \varepsilon)$ is a spin-charge symmetric fixed point (SC), $(0, \frac{5}{3}\pi^2 \varepsilon)$ (S) and $(\frac{8}{3}\pi^2 \varepsilon, 0)$ (C) are chiral-Heisenberg fixed points, as shown in Fig. 3. We now ask whether there is a stable spin-charge symmetric fixed point in the bosonic sector when $g_{s,c}$ are evaluated at the SC values. Indeed with this evaluation there are four bosonic fixed point as shown in Fig. 3, but only one is stable, providing us with a unique fixed point that captures the universal aspects of the quantum critical point in our lattice model.

By studying the renormalization of the field strength and boson mass, we can compute the critical exponents $\eta$ and $\nu$. The critical exponents at leading order in $\varepsilon$ are [19], $\eta = \frac{2}{3} \varepsilon$, $\nu = \frac{3}{10} \varepsilon$, $\beta = 2 - \frac{4}{5} \varepsilon$. We note that the quantitative agreement for these exponents between the one-loop $\varepsilon$-expansion and the numerical data is not great. But such discrepancy has been seen in other GNY type theories and can be attributed in part to the large
value of $\eta$.
