#### Abstract

NiO is a canonical Mott (or charge-transfer) insulator and as such is notoriously difficult to describe using density functional theory (DFT) based electronic structure methods. *Doped* Mott insulators such as NiO are of interest for various applications but rigorous theoretical descriptions are lacking. Here, we use quantum Monte Carlo methods, which very accurately include electronelectron interactions, to examine energetics, charge- and spin-structures of NiO with various point defects, such as vacancies or substitutional doping with potassium. The formation energy of a potassium dopant is significantly lower than for a Ni vacancy, making potassium an attractive monovalent dopant for NiO. We compare our results with DFT results that include an on-site Hubbard U (DFT+U) to account for correlations and find relatively large discrepancies for defect formation energies as well as for charge and spin redistributions in the presence of point defects. Beyond fitting to a single property, it is unlikely that single-parameter tuning of DFT+U will be able to obtain accurate accounts of complex properties in these materials. Responses that depend in subtle and complex ways on ground state properties, such as charge and spin densities, are likely to contain quantitative and qualitative errors.

#### I. INTRODUCTION

One of the outstanding problems in condensed matter physics is understanding the behavior of systems with strong electronic correlations. By "strong" we refer to correlations strong enough that standard theoretical and modeling techniques, such as non-interacting electrons or standard density functional-based theories, are inadequate to fully describe the system and yield substantially incorrect results when applied. Strongly correlated systems include, for example, fractional quantum Hall systems, heavy fermions, Kondo systems, but also a large number of transition metal oxides with partially filled 3d or 4d states. Of the 3d TMOs, NiO is a well-studied canonical example of a Mott insulator: strong correlations between the localized 3d-orbitals in the rocksalt structure drive the ground state of the system to an insulating type II antiferromagnetic coupling between successive Ni (111) planes. NiO has traditionally been considered a classic wide band gap Mott insulator<sup>1</sup>, while later works argued that NiO is a p-d charge transfer insulator<sup>2–5</sup>. More generally, NiO has been thought to possess an electronic structure intermediate to Mott insulators and p-d charge transfer insulators<sup>6,7</sup>.

Not only is NiO interesting from the perspective of a Mott or charge transfer insulator, but it is typically a *p*-type semiconductor, one of a very small number of *p*-type oxides, because as-deposited NiO typically has a Ni deficiency. As a *p*-type hole-doped oxide, it is interesting from a number of applications, ranging from transparent conducting oxides<sup>8-11</sup> to use in oxide electronics. Pristine stoichiometric NiO consists of Ni<sup>+2</sup> and O<sup>-2</sup> ions. Hole states can be generated and populated by increasing the concentration of Ni<sup>+3</sup> ions by adding defects, such as Ni vacancies or monovalent dopants.<sup>12</sup> Lithium is a well-known monovalent substitutional dopant, and Li-doped NiO (Li<sub>x</sub>Ni<sub>1-x</sub>O) has been studied intensively both experimentally and theoretically with a goal of determining its electronic and optical properties as an enhanced *p*-type transparent conducting oxide.<sup>13-19</sup> Measurements on Li<sub>x</sub>Ni<sub>1-x</sub>O grown by pulsed laser deposition (PLD) revealed that the resistivity of Li-doped NiO decreases monotonically to as low as 0.15  $\Omega$ -cm at room temperature with increasing Li concentration.<sup>20</sup> However, Li-doped NiO exhibits its minimum resistivity for a very Li dopant concentration (x = 0.07). This makes Li-doped NiO challenging to model using first-principle methods, whether density functional theory (DFT)<sup>16,18,21</sup> or many-body approaches, as a large unit cell in required, or some other method employed to incorporate a low Li concentration.

Potassium has been proposed more recently as a candidate monovalent dopant for NiO. Measurements on K-doped NiO grown by PLD indicate that the minimum room temperature resistivity of K-doped NiO is about 0.24  $\Omega$ -cm for  $K_{0.25}Ni_{0.75}O$  – a concentration that is significantly larger than the reported Li concentration at minimum resistivity, Li<sub>0.07</sub>Ni<sub>0.93</sub>O.<sup>22</sup> Although the minimum resistivity of K-doped NiO was measured to be slightly larger than that of Li-doped NiO, its minimum value is considerably smaller than reported values of the resistivity of NiO system doped with other monovalent dopants, such as sodium.<sup>23</sup> Because of the lack of theoretical information about the electronic properties in NiO system with substitutional dopants heavier than Li, e.g. K, it is not possible to have meaningful comparisons between point defect energetics, spin density, and other electronic properties of interest, in K-doped and Li-doped NiO. From a more general perspective, these properties in the presence of doping touch on a fundamental question in the field of strongly correlated systems: how do the electronic properties of a Mott insulator evolve upon doping? This is expected to be fundamentally different from doping standard semiconductors such as Si or GaAs, in which the electron-electron interactions are relatively weak and the electronic structure is mean-field like. As a consequence, the band structures of such semiconductors remain rigid as defect levels are added upon doping. In contrast, the entire electronic structure of a Mott insulator is expected to evolve upon doping. Understanding this evolution is of fundamental importance to understanding correlated systems, and is obviously also central to ever being able to use Mott insulators in a controlled way in applications. From this perspective, NiO can play the role of the simplest canonical Mott insulator, analogous to the role of the hydrogen atom in understanding atomic structure, in unraveling the physics of doped Mott insulators. However, this still hinges on the availability of computational methods that can accurately incorporate electronic correlations in realistic solid structures. One such method is the stochastic quantum Monte Carlo method (QMC). Relatively recent advances both in computer hardware as well as in algorithms and software have led to emerging applications of QMC to real, crystalline solids, typically with results that surpass DFT for systems with important electronic correlations such as transition metal oxides or systems where dispersive (van der Waals) interactions are important.<sup>24–38</sup> In this work, we use QMC to study the effect of point defects, a substitutional K dopant in antiferromagnetic type II (AFM-II) NiO, as well as the effect of a Ni or O vacancy. We calculate defect formation energies and also study how charge and spin densities are affected by the point defect. We also compare our results from those obtained within the DFT+U scheme of DFT. In particular, we compare the defect energetics as well as charge- and spin-density distributions. Perhaps not surprisingly, we find that DFT+U makes significant errors in the spin and charge distributions, especially on Ni atoms but also on O sites and on the K-site, where on the latter spin and charge densities from DFT+U are much smaller than those from DMC. These errors are at least in part due to the problem DFT-based approaches have in correctly obtaining both 3d charge- and spin-densities as well as the exchange-correlation energies stemming from these localized orbitals, especially in 3d TMOs.<sup>30,39</sup>

#### II. METHODOLOGY

In these QMC studies, we primarily employed the fixed-node Diffusion Monte Carlo (DMC) method<sup>40,41</sup> as implemented in the QMCPACK code.<sup>42</sup> In order to describe ionelectron and electron-electron correlations in the QMC trial wavefunctions, we used single Slater-Jastrow wavefunctions with one- and two-body variational Jastrow coefficients. Cutoffs for the one- and two-body terms were set at the Wigner-Seitz radius of the supercell, and B-spline coefficients were used. DFT single-particle Kohn-Sham orbitals for the initial QMC Slater determinant trial wavefunction were generated using a plane-wave basis set with the Quantum Espresso (QE) 5.3.0 code<sup>43</sup> with a 400 Ry kinetic energy cut-off and a  $4 \times 4 \times 4$ k-point grid. We used either the Perdew-Zunger<sup>44</sup> local spin density approximation (LSDA) or the Perdew-Burke-Ernzerhof (PBE) parametrization<sup>45</sup> of the generalized gradient approximation (GGA) exchange-correlation (XC) functionals. For the localized d orbitals, we used the DFT+U method<sup>46</sup> within which on-site Coulomb interactions are taken into account by a Hubbard correction.<sup>47</sup> We also compared the GGA+U calculations with calculations using the DFT+U formulation of Lichtenstein, Anisimov, and Zaane<sup>48</sup> with PBE GGA and one U and one J parameter with U=5.7 eV and J = 1.0 eV for NiO and K-doped NiO. The only discernible difference was that U+J led to a very slight increase in the localized Ni moment, from about 1.72  $\mu_B$  to 1.74  $\mu_B$ . Therefore, we based all our analyses on results using the simpler DFT+U formulation by Dudarev.

Norm-conserving pseudopotentials for this study (Ni, O, and K) were generated with a plane-wave basis-set using the OPIUM package.<sup>49</sup> The accuracy of the Ni pseudopotential

was already demonstrated in a previous DMC study for bulk AFM-II NiO.<sup>50</sup> In addition, the K pseudopotential in this study also provided excellent descriptions of the physical properties of bulk metal bcc K within DMC (see Supplemental Material<sup>51</sup>). In order to reduce the one-body finite size effects from the periodic supercell DMC calculations, we used twist-averaged boundary conditions (TABC).<sup>52</sup> In addition, we applied the modified periodic Coulomb (MPC) interaction<sup>53</sup> and Chiesa-Ceperley-Martin-Holzmann kinetic energy correction<sup>54</sup> to reduce the two-body finite size effects. Because DMC provides a "mixed" estimate of the density (a mixture between the fixed node density and the VMC one), we have corrected the mixed estimates by extrapolation to obtain "pure" estimates of the density, reflecting the fixed node wave function alone. This is a general property of the DMC method for operators that do not commute with the Hamiltonian. In order to obtain pure estimates of spin and charge density, we used the following extrapolation formula<sup>55</sup>:

$$\rho_{\rm est,X} = 2\rho_{\rm DMC,mixed,X} - \rho_{\rm VMC,X},\tag{1}$$

where X denotes spin or charge, and  $\rho_{\text{VMC},X}$  is the spin or charge density from the optimized VMC wavefunction.

Calculations to optimize the Hubbard U-parameter and for the equation of state for pure rock-salt NiO used a 16-atom supercell. For all other calculations, structural relaxations started by generating 64-atom supercells for NiO and NiO with a single substitutional K dopant. These supercells were relaxed (lattice parameters and internal coordinates) on a  $2 \times 2 \times 2$  k-point grid using FHI-aims<sup>56</sup> until the maximum Hellman-Feynman force on any one atom was below 0.005 Å/eV. The lattice constants for the 64-atom NiO and Kdoped NiO supercells were 8.397 and 8.445 Å, respectively. These cells as well as NiO with oxygen and nickel vacancies were subsequently subjected to relaxing the internal coordinates while keeping the lattice parameters fixed at the bulk values using GGA+U in the projector augmented wave (PAW) method<sup>57,58</sup> as implemented with the Vienna *Ab initio* simulation package (VASP)<sup>59,60</sup> with a kinetic energy cutoff of 400 eV and a  $2 \times 2 \times 2$  k-point grid. Structures were relaxed until the maximum Hellman-Feynman force on any atom was below 0.01 eV/Å. For further information, see Supplemental Material<sup>61</sup>.

 $VASP^{59,60}$  was only used for structural relaxation. All other reported values for GGA+U were obtained using Quantum Espresso<sup>43</sup> with the same norm-conserving pseudopotentials as the QMC calculations.

#### **III. RESULTS AND DISCUSSIONS**

The optimal value of the Hubbard U is usually chosen empirically by matching some specific electronic property such as the band gap to experimental values, or it is arrived at self-consistently<sup>62</sup>. The value of U will then typically depend on the specific XC functional used, with different XC functionals arriving at different values of U even for the same structural environment. While there exist DFT+U schemes with multiple parameters, *e.g.*, U-parameters on 3d and oxygen 2p orbitals, to fit different values such as band gap or defect energies, the cost of expanding the parameter set to optimize the DMC nodal surface can quickly become intractable and make the computational cost prohibitive. Moreover, the excellent comparison with experimental values that we obtain with a single U-parameter indicates that expanding the parameter space may not be worth the very large increase in computational cost.

In this work, for our DMC calculations we use U as a variational parameter in the QMC trial wavefunction: the best nodal surface is obtained by the optimal value of U which minimizes the total energy within DMC, e.g. as performed in Refs. [31],[30], and [29]. The amount of exact exchange in a hybrid functional can also be used in a similar way, see, for example Refs. [63] and [64].

In order arrive at an optimal U for the wavefunction nodal surface for AFM-II NiO, we computed the DMC total energy of NiO as a function of U. In the optimization, we used a

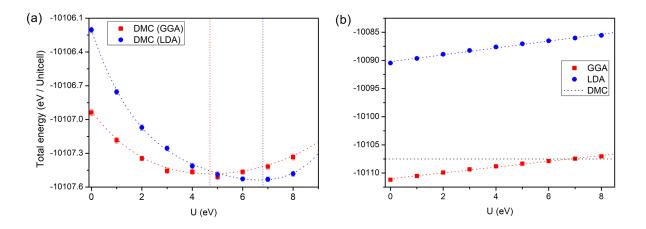

FIG. 1. (a) DMC total energy of NiO as function of U in the LDA and GGA trial wavefunction.(b) LDA and GGA total energy as function of value of U. The horizontal dotted line indicates the DMC total energy with the optimal value of U.

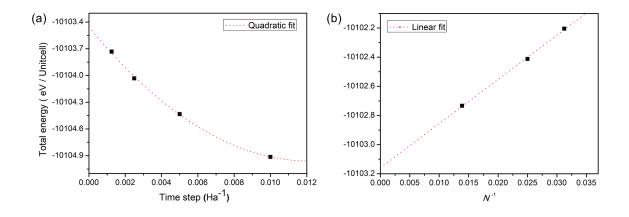

FIG. 2. (a) DMC total energy of AFM type II NiO as function of time step. The dotted line indicates a quadratic fit. (b) DMC total energy of NiO as function 1/N, where N is the total number of atoms in the supercell. The dotted line indicates a simple linear regression fit.

supercell consisting of eight formula units (f.u.) of NiO (16 atoms and 192 valence electrons total) in the DMC calculations (Fig. 1).

Figure 1(a) shows the calculated DMC total energy as function of Hubbard U for LDA+U and GGA+U trial wavefunctions. Without a Hubbard U (U=0), one can see that there is significant energy difference of 0.37(2) eV/f.u. between DMC total energies evaluated using LDA and GGA initial trial wavefunctions. As U increases, the DMC total energies decrease

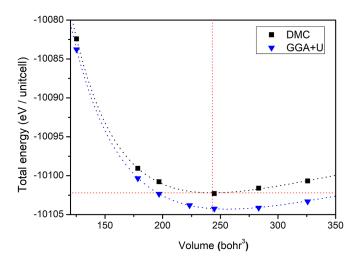

FIG. 3. GGA+U and DMC total energy of AFM type II NiO as function of unit cell volume. The red dotted line indicates the DMC total energy at the equilibrium unit cell volume as estimated by the Vinet fit.

TABLE I. Values of lattice constant (a), bulk modulus ( $B_0$ ), and cohesive energy ( $E_{coh}$ ) for AFM-II type NiO obtained from a Vinet fit of the equation of state (Fig. 3) computed using GGA+U and DMC at U=U<sub>opt</sub> and a 16-atom type II AFM NiO supercell.

method	a (Å)	$B_0$ (GPa)	$E_{coh}$ (eV/f.u.)
GGA+U	4.234	192	8.54
$DMC^1$	4.157(3)	196(4)	9.44(2)
DMC(current)	4.161(7)	218(14)	9.54(5)
$Experiment^2$	4.17	145-206	9.5

<sup>1</sup>Ref.<sup>50</sup>. <sup>2</sup>Ref.<sup>65</sup>.

rapidly as the wavefunction nodal surface is modified by the on-site Coulomb repulsion. Optimal values of U (U<sub>opt</sub>) were obtained through a quadratic fit to the LDA- and GGAbased energies, and were estimated to be 6.8(4) and 4.7(2) eV, respectively. Even though the optimal values for U are different for the LDA and GGA functionals, the minimum DMC energies obtained with the LDA and GGA wavefunctions at their respective  $U_{opt}$  are very close, -10107.54(1) eV/unit cell (LDA), and -10107.50(1) eV/unit cell (GGA). In contrast, and as expected due to the lack of a variational principle with respect to U, the DFT+U total energy increases with U both for LDA+U and GGA+U [Fig. 1(b)].

In order to assess the accuracy of the description of NiO obtained by DFT(GGA)+U at  $U_{opt}$  and DMC with the GGA+ $U_{opt}$  nodal surface, we calculated the equation of state (EOS) for AFM-II NiO using GGA+U and DMC. In the DMC calculations, time-step convergence and finite-size analysis were fully taken into account (Fig. 2). The DMC total energy at zero time step was obtained by extrapolating the DMC energy at DMC time steps of 0.01, 0.005, 0.0025, and 0.00125 Ha<sup>-1</sup> using a quadratic function [Fig. 2(a)]. Beyond full consideration of one-body finite size effects by applying TABC with a total of 64 twists, we additionally extrapolated the DMC results at zero time step to infinite size using eight, ten, and 18 f.u. supercells in order to remove two-body finite size effects [Fig. 2(b)].

From the calculated NiO total energies as function of volume of the unit cell, we obtained the equilibrium lattice parameter, bulk modulus, and cohesive energy using the Vinet function. The results for lattice parameter and bulk modulus using GGA+U and DMC are quite comparable (Fig. 3 and Table I). However, GGA+U significantly underestimates the cohe-

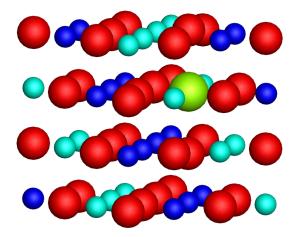

FIG. 4. Structure of 64-atom K-doped NiO. The red, blue, and teal spheres represent oxygen, and the two nickel spin species, respectively; potassium is represented the green sphere. The sizes of the spheres represent their ionic radii. Buckling of the oxygen atoms' positions near the potassium site is clearly visible.

sive energy compared to DMC and experimental values<sup>65</sup>. In contrast, the DMC-computed physical properties of AFM-II NiO are in excellent agreement with experimental results. Moreover, our DMC results evaluated using the DFT+ $U_{opt}$  trial wavefunction and nodal surface exhibit good agreement for the lattice constant and cohesive energy with previous DMC results<sup>50</sup> which used a DFT trial wavefunction without any Hubbard U<sup>66</sup>. This leads us to conclude that trial wavefunctions for NiO based on LDA or LDA+U orbitals experience a similar degree of fixed node error cancellation, despite the fact that a Hubbard U correction does result in a better nodal surface on the basis of the variational principle.

We now turn to K-doped AFM-II. GGA+U and DMC calculations were performed on the relaxed structure (relaxed using GGA+U as explained earlier) using the same value of  $U_{opt}$  (4.7 eV) as for NiO. We considered  $K_{0.03}Ni_{0.97}O$  including total 64 atoms (759 electrons) with K substituting one Ni. The concentration of K was significantly smaller than the reported maximum concentration of  $K_{0.25}Ni_{0.75}O$ .<sup>22</sup> A total of eight twists in TABC were used for K-doped NiO in order to eliminate one-body finite size effects. As can be seen in Fig. 4, the light oxygen atoms are displaced away from the K atom with the near-neighbor K-O bond increasing by 10.24% to 2.33 Å from 2.10 Å. In contrast, the displacement of the Ni atoms nearest the K site is negligible, only about 0.42 % from 2.96 Å to 2.99 Å.

With the relaxed NiO and K-doped NiO structures we first computed optical gaps for NiO and K-doped NiO to assess the effect of the K-dopant on the energy gap. Since the smallest energy gap within PBE+U calculation was observed at  $\Gamma$  symmetry point on the Brillouin zone of 64 atoms supercell, we also calculated the DMC direct gap at the corresponding symmetry point. The DMC optical gap can be estimated by computing  $E_{ph} - E_g$  where  $E_{ph}$  and  $E_g$  represents total energies of the state with a particle-hole excitation and of the ground state, respectively. The DMC value for  $E_{ph}$  was computed by promoting an electron from the valence state at the  $\Gamma$  symmetry point to the lowest conduction state in the initial trial wavefunction and subsequently preserving the nodal surface of the wavefunction under the fixed-node approximation. While we cannot prove that this excited state wavefunction will maintain its orthogonality to the ground state, this procedure is commonly used and in practice usually gives good results<sup>67,68</sup>.

It is not surprising that the GGA band gaps for NiO and K-doped NiO are found to be significantly smaller than values obtained from DMC or experiments, as can be seen in Table II. When a Hubbard U of 4.7 eV is introduced, the band gaps for both NiO and K doped NiO increase significantly, but the values are still smaller than experimental values of 4.3 eV. On the other hand, DMC significantly overestimates the optical gap for NiO compared to experimental values. Because of the possibility of large finite-size effects on the band gap, we also computed the NiO band gap using a larger supercell consisting of 128 atoms, for which the band gap was 5.0(7) eV. This value is likely smaller than the band gap using the smaller supercell, but the large statistical error for the 128-atom supercell does not permit us to conclusively claim that the band gap decreases with increasing supercell size. It is also likely still significantly larger than the experimental gap. Our DMC NiO band gap is larger than a previously-reported<sup>50</sup> DMC direct band gap evaluated without a Hubbard U in the trial wavefunction<sup>69</sup>. This lead us initially to speculate that the discrepancy between our DMC band gap and experiments may be due to a large fixed-node error in the excited state at Hubbard  $U=U_{opt}$ , where  $U_{opt}$  is the value that minimizes the DMC ground state energy. However, calculations of this energy gap as a function of U showed that the energy gap is fairly constant for U $\gtrsim 2.0$  eV (for details, see Supplemental Material<sup>70</sup>). Rather, we speculate that the large gap is mostly due to finite-size effects, which is partly supported by the results from the 128-atom supercell. On the other hand, on doping with K, we find that the band gap in NiO is significantly decreased by a substitutional K-dopant in the 64-atom

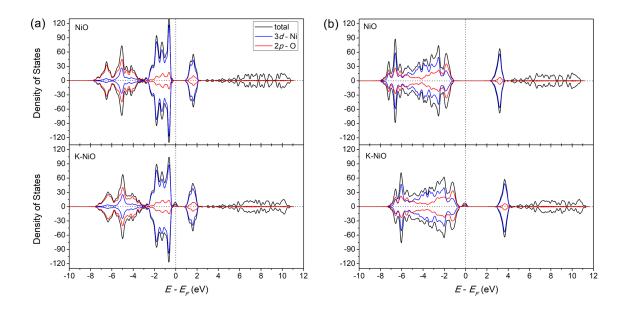

FIG. 5. Spin-resolved DOS and projected DOS on the Ni 3d and O 2p states for NiO and K-NiO using (a) GGA and (b) GGA+U. The K-dopant introduces states near the Fermi energy.

supercell, or 3% doping, both in DMC and GGA+U, by 1.1(5) and 0.7 eV, respectively. This is consistent with the DFT density-of-states (DOS), which indicate that the K-substitution leads to a state just above the lower Ni *d*-bands (Fig. 5). The GGA+U results indicate that K is an acceptor dopant, with an unoccupied state (hole) just above the Fermi surface. For comparison, experiments<sup>22</sup> found a decrease of 0.4 - 0.6 eV in the band gap with a 25% substitutional doping with potassium.

Next, we computed the formation energy  $E_f(K)$  of a K-dopant in NiO in order to assess the thermodynamic stability of K-doping. Using the standard equation<sup>71,72</sup>  $E_f(K) = E_{\rm KNiO} - E_{\rm NiO} - (\mu_{\rm K} - \mu_{\rm Ni})$ , where  $E_{\rm KNiO}$ ,  $E_{\rm NiO}$ ,  $\mu_{\rm K}$ , and  $\mu_{\rm Ni}$  represent the total energy of doped NiO, pure NiO, and chemical potential K of dopant and Ni, respectively. In general, the reference chemical potential is obtained from the total energy of the bulk system for the corresponding element, but the choice of reference for Ni chemical potential depends strongly on the growth conditions (O-rich or Ni-rich) used to make a NiO film. For O-rich conditions, the oxygen chemical potential  $\mu_O$  can be evaluated<sup>50</sup> by computing  $\mu_O \approx \frac{1}{2}E_{O_2}$ , where  $E_{O_2}$  is the total energy of an oxygen dimer. We can then calculate the Ni chemical potential ( $\mu_{\rm Ni}$ ) using the equilibrium condition of NiO,  $\mu_{\rm NiO} = \mu_{\rm Ni} + \mu_O$ . Note that we used the total energy of NiO as reference energy for  $\mu_{\rm NiO}$ . In contrast, the total energy of bulk Ni is required to obtain a reference energy for  $\mu_{\rm Ni}$  within Ni-rich condition. In this study,

TABLE II. Calculated formation energy of a K dopant  $(E_f)$  NiO under O-rich condition, and optical gap  $(E_g)$  for NiO and K-doped NiO in a 64-atom supercell. Energies are given in units of eV.

we focused on the formation energy under O-rich condition due to potential uncertainties in describing the bulk ferromagnetic Ni metal in DMC with a single Slater determinant. We calculated the reference energy for the K chemical potential including contributions from the ionic bonding between K<sup>+</sup> and O<sup>-2</sup> ions using the equilibrium condition  $\mu_{K_2O} = 2\mu_K + \mu_O$ , where  $\mu_{K_2O}$  denotes the chemical potential of bulk anti-fluorite K<sub>2</sub>O that can be obtained from the total energy of the corresponding structure.

Table II shows the calculated formation energy of a substitutional K-dopant near the center of a 64-atom supercell. Both the GGA+U and the DMC formation energies for a potassium substitutional dopant are significantly smaller than the formation energies for oxygen or nickel vacancies under oxygen-rich conditions (see below), indicating a relative stability of K-doping under those conditions. Also, the GGA+U K-dopant formation energy is found to be significantly smaller than the DMC formation energy. This is consistent with GGA+U underestimating the cohesive energy for NiO compared to DMC (and experiments). However, the difference in K-dopant formation energy between GGA+U and DMC is about 46%, compared to the much smaller 10% difference in cohesive energy of NiO.

In order to visualize the electron spin density distributions in the presence of a sub-

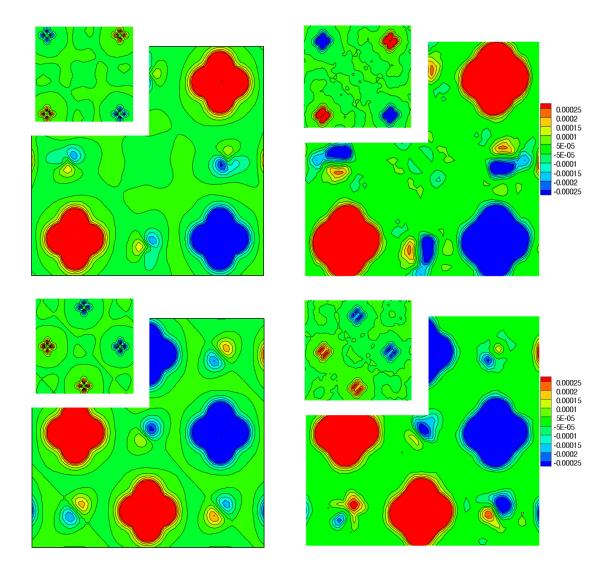

FIG. 6. 2D contour plots of GGA+U (top left) and DMC (top right) spin densities in the (001) basal plane containing the K-dopant in K-doped NiO in units of Å<sup>-3</sup>. The K dopant is located at the center in the contour plots. The lower panels show the corresponding spin densities in a lower (001) basal plane without a K dopant. The insets show the same densities on a scale from -0.0075 to 0.0075 Å<sup>-3</sup>.

stitutional dopant and to analyze any discrepancy between the GGA+U and DMC spin densities, we calculated the total electron charge density  $\rho_{charge} = \rho_{up} + \rho_{down}$  and spin density  $\rho_{spin} = \rho_{up} - \rho_{down}$ , where  $\rho_{up}$  and  $\rho_{down}$  represent the charge density for up- and down-spin electrons, respectively. Figure 6 shows spin densities for K-doped NiO obtained using GGA+U and DMC, and Fig. 7 shows the difference in spin density between DMC and GGA+U. In order to reduce the noise in the DMC spin densities, we averaged them over symmetries and also filtered some high-frequency spatial noise (see Supplemental Material<sup>76</sup> for details). The figures show a weak induced 2p spin density on the oxygen sites, with a total moment of zero. While the DMC data are noisier because of the statistical sampling, the induced spin densities are larger on the oxygen sites for DMC than for GGA+U. Furthermore, in GGA+U, the spin density at the K-site is completely negligible; in DMC it is clearly non-zero but small. The lower panels of Fig. 6 clearly show the arrangement of the Ni  $3d_{x^2-y^2}$  orbitals and the oxygen 2p orbitals leading to antiferromagnetic superexchange between the Ni sites. Note that the oxygen 2p orbitals In GGA+U are aligned along the (110) direction (diagonally in the figure) and not along the (100) direction. There is some distortion in the GGA+U spin density on the oxygen sites (lower left panel of Fig. 6), especially directly under the dopant. The DMC spin densities on the oxygen sites show more distortion, especially on the (110) line (lower right panel of Fig. 6). In the plane of the K dopant, the oxygen 2p orbitals are clearly distorted (top panels of Fig. 6) and aligned directly along the (100) and (010) directions connecting nearest antiferromagnetically arranged Ni sites around the K site. The bottom panels also indicate that there is a slight difference in the spin density on the oxygen site at the center of the planes – this site is directly underneath the K site, and this oxygen spin density is not symmetric across the (110) line with more negative (blue) than positive spin density. The distortion of the oxygen 2p orbitals near the K site is captured qualitatively both by the GGA+U and DMC calculations but is quantitatively different because of the larger induced spin density in the oxygen 2p orbitals in DMC. In Fig. 8 is shown a 1D plot of the charge density obtained along the (111) direction by applying all 48 rotational symmetry operations corresponding to cubic symmetry to the charge-density centered around the central Ni (left panel) or the impurity atom (right panel). The figure shows the charge density at the central K atom is rather delocalized, and also shows a small change (decrease) in charge density on the near-neighbor oxygen sites (small bumps near 3.66 and 10.97 Å) as well as increased charge on the Ni sites (near 0.00 and 14.63 Å)). The hole density arising from the monovalent dopant primarily resides on the K site with additional charge distortions on O and Ni sites in the supercell.

Figure 7 shows contour plots of the spin density difference between the DMC and GGA+U calculations. The left panel shows the spin density difference in a (001) basal plane not containing the K dopant, and the right panel shows the spin density difference in the central (001) plane containing the K dopant, with the K site at the center of the figure. The figure

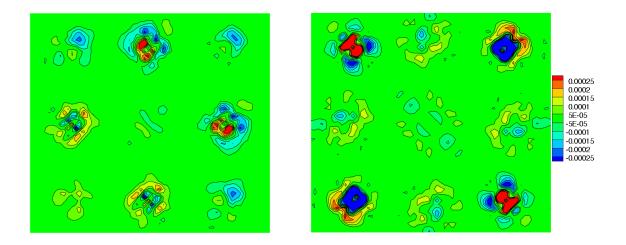

FIG. 7. 2D contour plots of the difference between DMC and GGA+U spin densities. The left panel shows the spin density difference at a (001) basal plane below the central plane with the K dopant; the right panel shows the spin density difference in the central (001) plane with the K dopant at the center of the figure. The color scale goes from -0.00025 Å<sup>-3</sup> to +0.00025 Å<sup>-3</sup>. The DMC Ni spin densities are slightly more extended than the GGA+U ones.

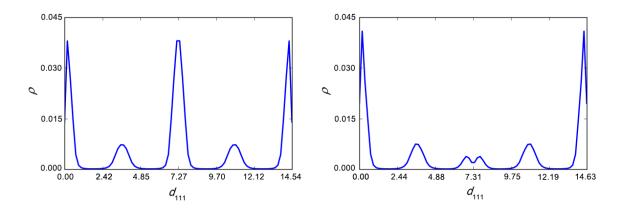

FIG. 8. 1D symmetrized plots of the charge density in units of Å<sup>-3</sup> along the (111) direction ( $d_{111}$  in units of Å) in NiO (left panel) and K-doped NiO (right panel) with central Ni (left panel) or K (right panel) atom. The figures show an increase in the Ni charge in the presence of K (right panel near 0 and 14) as well as a small polarization on the O sites (right panel near 3 and 10).

clearly shows a difference in the spin density on the Ni sites: the DMC spin density is less than the DFT+U one near the Ni cores, but the DMC spin density is more extended (this shows up as, e.g., a blue layer around the red core as at the top Ni site in the left panel of Fig. 7). The right panel of Fig. 7 shows this difference between DMC and GGA+U Ni spin densities is increased in the plane of the dopant.

In order to quantify the spin and charge density differences between the DMC and GGA+U results, we computed the root-mean-square deviation (RMSD) of charge and spin densities as follows,<sup>77</sup>

$$RMSD(\rho) = \sqrt{\frac{\sum_{i=1}^{N} (\rho_{DFT}(R_i) - \rho_{DMC}(R_i))^2}{N}},$$
(2)

where  $\rho_{DFT}(R_i)$ ,  $\rho_{DMC}(R_i)$ , and N denote the DFT and DMC charge or spin density at grid point  $R_i$ , and total number of grid points, respectively. The results are shown in Table III. The calculated RMSD( $\rho_{charge}$ ) and RMSD( $\rho_{spin}$ ) for NiO and K-doped NiO are almost identical: there are differences between DMC and GGA+U charge and spin density distributions but the presence of the K dopant does not significantly change the average of charge and spin density distributions in the supercell, as indicated by the first two rows in the Table. In order to quantify the charge and spin density differences between DMC and GGA+U on the Ni and O sites (Fig. 7), we computed the charge and spin density RMSD in spherical volumes with a radius equal to half the Ni-O bond length (1.16 Å) centered on the Ni sites,  $\rho_{type}^{Ni}$ , or the O sites,  $\rho_{type}^{O}$ , where type is charge for the charge density and

TABLE III. Calculated RMS deviation of spin and charge electron densities for NiO and K-doped NiO. The statistical errors in the RMSDs are below  $10^{-7}$ .

	NiO	K-doped NiO
$\text{RMSD}(\rho_{spin}) \ (10^{-3})$	0.061	0.077
$\text{RMSD}(\rho_{charge}) \ (10^{-3})$	0.148	0.155
$\text{RMSD}(\rho_{charge}^{Ni})~(10^{-3})$	1.106	1.154
$\text{RMSD}(\rho^O_{charge})~(10^{-3})$	0.193	0.219
$\text{RMSD}(\rho_{charge}^{Ni(NN)})~(10^{-3})$	-	1.131
$\text{RMSD}(\rho_{charge}^{O(NN)})~(10^{-3})$	-	0.197
$\text{RMSD}(\rho_{spin}^{Ni})~(10^{-3})$	0.376	0.435
$\mathrm{RMSD}(\rho^O_{spin})~(10^{-3})$	0.135	0.174
$\text{RMSD}(\rho_{spin}^{Ni(NN)})~(10^{-3})$	-	0.433
$\text{RMSD}(\rho_{spin}^{O(NN)})~(10^{-3})$	-	0.163
$\text{RMSD}(\rho_{spin}^K)~(10^{-3})$	-	0.093

spin for the spin density. We also calculated RMSD values for charge and spin densities average only over the Ni or O sites that are near neighbors to the K-dopant site, denoted  $\text{RMSD}(\rho_{type}^{X(NN)})$ , where X is Ni or O. We first discuss the RMSD values for charge densities. There is little change  $\text{RMSD}(\rho_{charge})$  in the presence of the dopant: while there are difference between DMC and GGA+U charge densities, they are not significantly changed over the whole supercell. In contrast,  $\text{RMSD}(\rho_{charge}^{Ni})$  and  $\text{RMSD}(\rho_{charge}^{O})$  do change in the presence of the dopant, especially  $\text{RMSD}(\rho_{charge}^{Ni})$ . This indicates that the charge distribution on the Ni sites changes more in DMC in the presence of the dopant than it does in GGA+U. On the other hand, there is a much smaller difference between  $\text{RMSD}(\rho_{charge}^{Ni})$  and  $\text{RMSD}(\rho_{charge}^{Ni(NN)})$ , and between the corresponding RMSD values for O. This leads us to conclude that the difference in charge distribution between DMC and GGA+U when the dopant is introduced is not confined primarily to sites near the dopant but is more evenly distributed throughout the supercell.

Next, we discuss the RMSD values for the spin density. We will just focus on the Ni spins as an analysis of the O spins is entirely analogous. The  $\rho_{spin}^{Ni}$  RMSD is significantly larger, 0.435, than the supercell spin density RMSD, RMSD( $\rho_{spin}$ )=0.077, consistent with the Ni spin density difference shown in Fig. 7. Moreover, RMSD( $\rho_{spin}^{Ni}$ ) increases more in the presence of the dopant, from 0.376 to 0.435, than the corresponding supercell value RMSD( $\rho_{spin}$ ) (0.061 to 0.077). This shows that there is indeed a quantifiable, but small, difference in the Ni spin redistribution between DMC and GGA+U in the presence of the dopant. On the other hand, the difference between the near-neighbor spin RMSD, RMSD( $\rho_{spin}^{Ni(NN)}$ ) = 0.433 and RMSD( $\rho_{spin}^{Ni}$ ) = 0.435 in the presence of the dopant is small; just as for the charge density, the difference between DMC and GGA+U Ni spin densities in the presence of the dopant. Finally, RMSD( $\rho_{spin}^{K}$ ) = 0.093 shows, as expected, a difference between the DMC and GGA+U spin distribution on the K site.

In order to correlate differences between DMC and GGA+U (spin) density with total energy differences, we recall that the GGA+U total energy for NiO is close to the DMC total energy with  $U=U_{opt}$ . In view of the more compact DMC Ni spin densities and the larger DMC oxygen 2p spin densities, this suggests that there is an error cancellation in GGA+U between more extended Ni spin densities than in DMC, but smaller oxygen 2pspin densities. On the other hand, the formation energy of the K dopant is much smaller

TABLE IV. Calculated formation energies in eV of a single neutral O and Ni vacancy in NiO under oxygen-rich conditions, and spin density RMSD on the Ni sites.

 $^{1}$ Reference<sup>50</sup>.

in GGA+U (0.59 eV) than in DMC (1.29 eV). This makes us speculate that the difference in dopant formation energy originates primarily in the DMC spin density on the K site, as GGA+U has no discernible spin density on the K site, coupled with a much smaller difference in spin densities throughout the supercell.

Finally, we discuss formation energies of Ni (O) neutral vacancies in NiO under oxygenrich conditions, as well as spin and charge densities of systems with a Ni vacancies. We here consider formation of a Ni (O) vacancy in NiO under O-rich condition. We removed a Ni (O) from the 64-atom NiO supercell and relaxed the internal coordinates of the resulting structure. The formation energy  $E_f$  of a neutral single vacancy in NiO can be calculated as  $E_f = E_{\text{NiO:vac}} - E_{\text{NiO}} + \mu_{\text{vac}}$ , where  $E_{\text{NiO}}$ ,  $E_{\text{NiO:vac}}$ , and  $\mu_{\text{vac}}$  are the total energy for NiO with a defect, total energy for stochiometric NiO, and chemical potential of the vacancy species (Ni or O).

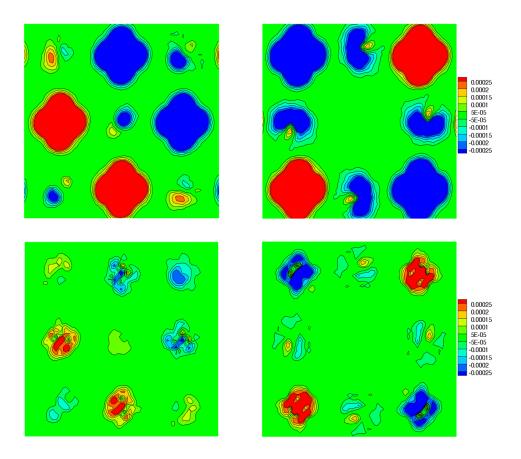

FIG. 9. 2D contour plots of the DMC spin density in units of  $Å^{-3}$  on the (001) basal plane without a NiO vacancy (upper left) and of the (001) basal plane containing a single neutral Ni vacancy (upper right). The Ni vacancy is located at the center of the panel. The lower panels show the difference between the DMC and GGA+U spin densities in the same planes.

DMC and DFT+U formation energies for neutral O  $[E_f(O)]$  and Ni  $[E_f(Ni)]$  vacancies in NiO as well as RMSD values for charge and spin density distributions are summarized in Table IV. The GGA+U value, 6.2 eV, for  $E_f(O)$  with the Hubbard U at U=U<sub>opt</sub> is smaller than the previously reported DMC value, 7.2 eV, using a U=0 trial wavefunction and nodal surface<sup>50</sup>. However, we note that our computed values for  $E_f(O)$  using GGA+U and DMC are comparable at 6.2 eV and 6.6 eV, respectively. This leads us to conclude that GGA+U with U=U<sub>opt</sub> does a reasonably good job to describe not only the ground state energy of NiO but also the energetics of single neutral oxygen vacancies. In contrast the DMC formation energy  $E_f(Ni)$  for the neutral Ni vacancy is significantly larger (and positive) at 3.5 eV than the GGA+U energy, which is negative (-0.9 eV). This latter would imply that neutral Ni vacancies would form spontaneously under oxygen-rich conditions.

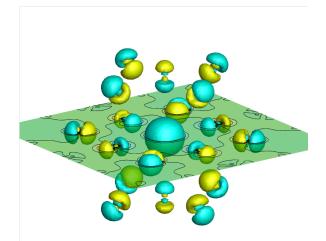

FIG. 10. 3D iso-surface plot of the difference between the GGA+U charge density with and without the Ni vacancy. The iso-surfaces are at  $\pm 0.002$  Å<sup>-3</sup> with gold(teal) positive (negative).

This is in disagreement with calculations of defect energies by Zhang *et al.*,<sup>78</sup> using GGA+U with both U and J parameters. However, Zhang *et al.* used U=6.3 eV and J = 1 eV and a less stringent condition on geometry optimization (Hellman-Feynman forces relaxed to within 0.05 eV/Å). We know from our own calculations that not relaxing the geometry with a Ni vacancy increases its formation energy rather substantially from -0.9 eV to +0.1 eV. Furthermore, the NiO bandgap obtained by Zhang *et al.* was 3.1 eV, considerably lower than the experimental value of 4.3 eV and our own GGA+U value of 3.59 eV. We believe that the more stringent conditions on our GGA+U calculations lead to a more accurate value for  $E_f(Ni)$  within GGA+U. Therefore, we conclude that GGA+U erroneously gives a negative formation energy for a neutral Ni vacancy point defect under oxygen-rich conditions.

Figure 9 top row depicts the DMC spin density in a basal (001) plane without (left panel) and with (right panel) the Ni vacancy. The bottom row panels depict the corresponding spin density difference between DMC and GGA+U. The top left panel now clearly shows an asymmetric spin density at the central O site with a net negative spin density. Similarly, the top right panel indicates a negative spin density on the oxygen sites: this suggests that the hole density is primarily located on the oxygen sites near-neighbors to the Ni vacancy. In addition, the bottom row of Fig. 9 shows that the DMC Ni spin densities is larger than the GGA+U and that the DMC oxygen spin density in the plane of the vacancy is more localized towards the vacancy than the GGA+U. Figure 10 shows a 3D

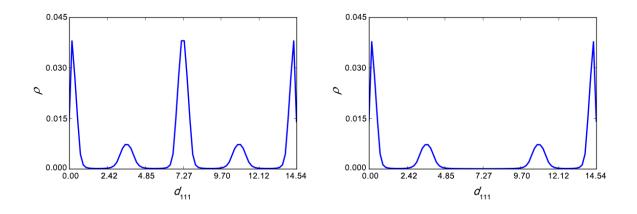

FIG. 11. 1D symmetrized plots of the charge density in units of Å<sup>-3</sup> along the (111) direction  $(d_{111} \text{ in units of Å})$  in NiO (left panel) and NiO with a Ni-vacancy at the center (right panel) with central Ni (left panel) or Ni-vacancy (right panel) atom. The figures shows a lack of hole charge accumulation as seen in K-doped NiO, with a very slight decrease in the Ni charge in the presence of a Ni-vacancy (right panel near 0 and 14).

depiction of iso-surfaces of the difference in charge density between the system with and without a Ni vacancy. The "dumbbells" are all pointing towards the vacancy site, with the oxygen dumbbells' negative charge (charge repelled from the vacancy) pointing towards the vacancy, and the Ni dumbbell's positive charge pointing towards the vacancy. This is just a manifestation of the fact that Ni near the vacancy relaxes inward toward the vacancy, whereas and near the vacancy relaxes outward away from the vacancy. The symmetry of the dumbbells suggests that there is little net charge changed on the oxygen and Ni sites, in contrast with the spin density in Fig. 9. Figure 11 shows the 1D symmetrized graphs of the charge density along the (111) direction in the NiO supercell (left panel) for comparison, and in the supercell with a central Ni vacancy (right panel). Also in contrast with the K-doped supercell, the symmetrized Ni vacancy resides primarily on the vacancy site with some charge density from the Ni vacancy resides primarily on the vacancy site with some charge distortions on the Ni sites throughout the supercell.

We concluded earlier that the incorrect spin and charge distributions in GGA+U led to underestimating the formation energy of a K dopant withing GGA+U. Similarly, we conclude that the large discrepancy in the formation energy of a Ni vacancy within GGA+U compared to DMC can be understood to arise from the qualitatively and quantitatively different charge and spin density distributions on the Ni sites where a large value of the RMSD parameters were observed. As can be seen in Table IV, the  $\text{RMSD}(\rho_{spin}^{Ni})$  and  $\text{RMSD}(\rho_{spin}^{Ni(NN)})$  are both large at about 0.4. Both increase in the presence of the Ni vacancy, but  $\text{RMSD}(\rho_{spin}^{Ni(NN)})$ increases more, from 0.395 to 0.440 – the Ni vacancy has a larger impact on the spin re-distribution than does the substitutional K dopant, and this re-distribution is poorly captured by DFT+U. Similarly, the spin distribution on the oxygen sites are relatively poorly captured by DFT+U with  $\text{RMSD}(\rho_{spin}^{O})$   $\text{RMSD}(\rho_{spin}^{O(NN)})$  being similar at 0.160 and 0.163, respectively, for NiO. These values *decrease*, however, to 0.132 and 0.119 in the presence of the Ni vacancy, indicating a smaller difference between the GGA+U and DMC oxygen spin density distributions in the presence of the vacancy.

#### IV. CONCLUSIONS

In summary, we have used highly accurate DMC as well as the DFT+U (GGA+U) method to study AFM type II NiO and its point defects, potassium substitutional dopant, and Ni and O vacancies. A potassium dopant (single hole) and Ni vacancy (two holes) point defects both lead to spin-and charge-redistributions extending well beyond near neighbors to the point defect. However, for the potassium dopant the charge redistribution is both on oxygen and Ni sites, while for the Ni vacancy, it is primarily on Ni sites. Our calculations, both using PBE+U and QMC, show that a low dopant concentration significantly lowers the energy gap, consistent with previous experiments<sup>22</sup>. However, the energy gap for NiO obtained using diffusion Monte Carlo is significantly larger than experimental values as well as previous results using diffusion Monte Carlo.<sup>50</sup> Calculations of the gap as function of U as well as for a 128-atom supercell suggest that finite-size effects contribute to this discrepancy. The defect formation energies for a K dopant and Ni vacancy differ considerably between GGA+U and DMC. By comparing RMS differences for charge and spin densities between DMC and GGA+U, both for the whole supercell as well as for local Ni and O sites, we conclude that the difference in defect formation energy arises primarily from the the difference in spin densities on the Ni 3d orbitals obtained from GGA+U and DMC, with a smaller contribution from differences in O 2p spin distributions; in these cases, because of the distorted spin distributions compared to the defect-free systems, error cancellation is much smaller in GGA+U which increases energy differences compared to DMC. From

our results, we also conclude that previously obtained point defect formation energies based on DFT schemes are underestimated.<sup>50,78,79</sup> Previous predictions of energetic stability of point defects in NiO using typical DFT+U functional were too optimistic as compared to DMC results. Correcting DFT schemes to better account for defect formation energies will obviously require a delicate balance between obtaining better spin densities and the concomitant energy changes. At the same time, it is likely such corrections to improve defect formation energies may lead to worse estimates of other electronic properties, such as the band gap. It would be interesting in future work to compare the electronic properties obtained in DFT schemes using DMC charge densities, similar to the so-called HF-DFT scheme, in which Hartree-Fock densities are used to evaluate DFT energies.<sup>80</sup> The HF-DFT scheme has been shown to yield significantly better energies for so-called spin-crossover complexes<sup>81</sup>. These complexes have a small energy difference between high- and low-spin states that DFT fails to obtain, often even getting the wrong sign for it. In contrast, HF-DFT energies are very close to benchmark DMC energies.<sup>82</sup> As in our work here on NiO, the difficulty for DFT to deal with spin-crossover complexes has been traced to the relatively poor DFT description of the Fe 3d orbital in these complexes. A systematic study of DMC-DFT energies may lead to a fruitful avenue to improve DFT, at least for third row transition metal complexes, by correcting its densities, especially those on localized 3d orbitals.

- <sup>66</sup> In Ref. 50, all production calculations were performed with LSDA orbitals generated with fixed (insulator-like) occupations during the SCF cycle. In pre-production calculations aimed at exploring the effect of a Hubbard U parameter on the nodal surface, the U-parameter was erroneously set to zero in the trial wavefunctions due to a software error. As a consequence, Ref. 50 incorrectly concluded that a U parameter has no measurable effect on the DMC total energy. Plain LSDA was then selected and used consistently for all production calculations in that work.
