Abstract

Interfacial characteristics are critical to various properties of two-dimensional (2D) materials such as band alignment at a heterojunction or nucleation kinetics in a 2D crystal. Despite the desire to harness these enhanced interfacial properties for engineering new materials, unexpected phase transitions and defects, unique to the 2D morphology, have left a number of open questions. In particular, the effects of configurational anisotropy, which are difficult to isolate experimentally, and their influence on interfacial properties are not well understood. In this work, we begin to probe this structure-thermodynamic relationship, using a rotating magnetic field to generate an anharmonic interaction potential in a 2D system of paramagnetic particles. At low magnetic field strengths, weakly interacting colloidal particles form non-close-packed, fluid-like droplets, whereas, at higher field strengths, crystallites with hexagonal ordering are observed. We examine spatial and interfacial properties of these 2D colloidal clusters by measuring the local bond orientation order parameter and interfacial stiffness as a function of interaction strength. To our knowledge, this is the first study to measure a tunable interfacial stiffness of a 2D colloidal cluster by controlling particle interactions using external fields.

I. INTRODUCTION

Novel two-dimensional (2D) materials have garnered significant interest due to their enhanced optical, electrical, chemical, and mechanical properties [1–4]. On the other hand, changes in molecular structure, chemical composition, or concentration can lead to unexpected phase transformations which subsequently impacts the performance of such materials. For example, it is known that a change in the temperature of a system results in thermal expansion; however, since this expansion directly affects both the thermodynamics and kinetics of the system, it has been difficult to decouple the influence on the material’s spatial configuration.

In an effort to investigate these phenomena, colloidal systems have been widely proposed as appropriate models for molecular systems. This has yielded new information concerning the thermodynamics and phase behavior of confined planar 2D systems [5–9], and more recently, newly investigated phenomena such as interfacial premelting with temperature dependent colloidal particles [10] have shown the importance of interfacial dynamics on 2D material properties. Thus far, the majority of interfacial studies of colloidal systems utilize interactions represented by either charged particles, hard-spheres, or depletion interactions [10–12]; however, many of the interesting properties of 2D molecular systems are governed by longer-range anharmonic interactions. Colloidal systems with tunable long-range interactions can be generated with magnetic and electric fields, but few studies have probed the resulting interfacial properties as a function of interaction strength.

Recently, magnetic Janus particles in a rotating magnetic field have been shown to form colloidal crystals with a melted interface induced via a shear force [13] illustrating how dislocations in the bulk crystal migrate to the interface. In this work, we generate 2D colloidal clusters with a tunable long-range anharmonic interaction potential, and we characterize their energetics as well as their interfacial properties as a function of interaction strength (see supplementary material (SM) video of the colloidal cluster shown in real time). We find that the thermodynamic quantities are independent of cluster size for the ranges used in this study (300 to 1500 particles). We begin by finding the excess internal energy of the clusters using a modified dipole model followed by a measurement of the interface fluctuations to calculate the excess free energy. These values can then be used in the Helmholtz free energy equation to obtain the excess entropy for each cluster. The finite size of the colloidal
clusters allows us to simultaneously investigate both bulk and interfacial 2D properties. Of particular interest is understanding how increasing intermolecular interactions increases the configurational anisotropy of the interface, which in turn leads to a variability in the line tension in crystallites. This has significant implications for highly correlated 2D materials where interface anisotropy impacts various transport properties within the material [14, 15].

II. CLUSTER ENERGETICS

Under uniform magnetic fields, charged paramagnetic particles interact anisotropically with long-range dipolar attraction and short-range Derjaguin-Landau-Verwey-Overbeek (DLVO) repulsion. When placed in a high frequency rotating magnetic field, the dipolar interaction is azimuthally averaged about each particle. This leads to a modified version of the dipole model that is independent of the angle between particle pair and magnetic field vectors [16] which we use to characterize the internal energy of our system. This model has also been verified through experimental measurements using inverted Boltzmann analysis of the interparticle spacing (see ref.[16] and SM for the equations).

A high frequency (20Hz) rotating magnetic field is applied to assemble 2D colloidal clusters using a suspension of 1.1 $\mu$m diameter carboxyl-coated paramagnetic particles which are placed in a flow cell between two pairs of orthogonal solenoid coils. Under an applied magnetic field, the particles begin to aggregate and assemble into two-dimensional clusters that grow to be tens of microns in diameter [Fig.1(a)]. In order to quantify the internal energy of each cluster, we begin by using a dipole model to calculate the internal energy of each particle [17]. Using this model, the net internal energy between the paramagnetic colloids can be approximated by the anharmonic interaction potential [Fig.1(b)]: 

$$u(r) \sim \frac{A}{r^3}$$

where $r$ is the center to center distance between the particle pair and $A$ is a function of particle size, magnetic susceptibility, and magnetic field strength [17].

In order to compare this interaction potential to the thermal energy of the system, we write our energies in multiples of $k_bT$. The magnetic field strength selected for this set of experiments range from 8 to 12 Gauss which corresponds to pair potentials with well depths ($|u_0|$) ranging from 5.2 $k_bT$ to 11.7 $k_bT$. Note that these values are reported as the inverse of the effective temperature, $T_{eff} = k_bT/|u_0|$, which is typically used in colloidal systems to more readily compare the magnitude of the interaction energy. In this study, $T_{eff}$ ranges

from 0.19 at 8 Gauss to 0.085 at 11 Gauss.

In a 2D system, the colloidal clusters prefer to form circular shapes to minimize their line tension, analogous to the minimization of interfacial tension in 3D. We define line tension, $\gamma$, as the mechanical work required to increase the interface length which is a thermodynamic quantity that is independent of molecular structure [18]. The cluster is a single-component system at quasi equilibrium with constant temperature, $T$, cluster area, $A$, and number of
particles, \( N \). The configuration of a cluster at equilibrium is determined by minimization of the Helmholtz free energy, \( F \), at the Gibbs interface [19]:

\[
\frac{F^\sigma}{l} = \gamma + \sum_i (\mu_i \Gamma_i)
\]

(1)

Here, \( F^\sigma/l \) is the excess Helmholtz free energy per unit length, \( l \), i.e. the excess at the Gibbs dividing surface, \( \sigma \), compared to the bulk value. At the interface, the Gibbs excess adsorption, \( \Gamma \), is zero; thus, line tension is equal to the Helmholtz free energy per length.

In order to compare our energy calculations independently of interfacial length and cluster size, we normalize our values by a unit length that divides the cluster into sector cells where the arc length of each cell is defined by a single particle (see SM for details).

The second thermodynamic relationship to consider is the Helmholtz free energy; the difference between the potential energy of the system, \( U \), and \( TS \) where \( S \) is the entropy. By writing the equation in its excess form (\( F^\sigma = U^\sigma - TS^\sigma \)) and given \( F^\sigma \) and \( U^\sigma \), we find the excess entropy of a cluster, a parameter that is experimentally challenging to obtain. Since the kinetic energy remains constant throughout the cluster, the excess kinetic energy goes to zero and \( U^\sigma \) becomes solely governed by the anharmonic interaction potential between the particles.

Cluster stability is characterized by examining the potential energy distribution within a given cluster. Fig.1(c) shows a potential energy landscape for a given cluster and the energies of individual particles are illustrated by using a bicolor gradient scheme. Note that since the energy calculation depends on the neighboring particles, any topological defects will also affect the energy of the neighboring particles. The radial change in the cluster’s potential energy per unit length is defined as \( E \):

\[
E(R) = U^\sigma/l = [\bar{u}(R) - \bar{u}_b]/l
\]

(2)

Here, \( \bar{u}_b \) is the energy in the bulk averaged over particles a distance, \( R \), away from the center of the cluster. The particles in the bulk phase have the lowest potential energy \( (u_{min}) \), whereas the energy of the particles increases when approaching the interface as they begin to experience a change in the configuration of their neighboring particles as shown in Fig.1(d).
III. CLUSTER TUNABILITY AND INTERFACIAL STIFFNESS

A. Cluster tunability

By increasing the strength of the magnetic field, and by extension the well-depth of the particle pair potential, the clusters transition from a disordered fluid-like state to an ordered crystalline state. We quantify the change in the energetics and spatial characteristics of single 2D colloidal clusters using the analytical methods described in section II. Fig. 2 shows a cluster containing 710 to 730 particles at interaction potentials of $5.8 \ k_bT$ [Fig. 2(a)], $6.6 \ k_bT$ [Fig. 2(b)], and $9.8 \ k_bT$ [Fig. 2(c)].

At a relatively low well-depth of $5.8 \ k_bT$, particles throughout the entire cluster form a fluid-like disordered phase as shown in Fig. 2(d). Upon increase of the potential well depth, a well-ordered microphase forms in the center of the cluster surrounded by a disordered exterior layer. For clusters with more than 200 particles, the thickness of the disordered exterior becomes independent of cluster size and is only dependent of the well depth. As the magnetic field is further strengthened, the crystalline microphase begins to grow towards the interface resulting in a decrease in the thickness of the disordered boundary layer until it reaches a thickness of 1-2 particle diameters as shown in Fig. 2(f). The radial change in packing density, $\eta$, and $\psi_6$ are also plotted for each of the clusters [Figs. 2(g)- 2(i)].

The characteristic interfacial width $W_{10-90}$, which scales with particle diameter, $D$, was found using $\eta$ and has also been shown to decrease with increasing magnetic field strength [20]. At well depths of $5.8 \ k_bT$, $6.6 \ k_bT$, and $9.8 \ k_bT$, $W_{10-90}$ is $6.55 \ D$, $6.09 \ D$, and $5 \ D$. The surface excess energy per unit length is calculated using Eq. 3 for each of the three states, and we find $E$ to be $7.2 \pm 0.69 \ k_bT/D$, $14.2 \pm 1.21 \ k_bT/D$, and $22.4 \pm 1.25 \ k_bT/D$ respectively. As the cluster becomes less like a fluid and more like a crystal, it begins to deviate away from a circular shape to a more faceted structure. Such azimuthally anisotropic interfaces [Fig. 2(c)] lead to less accurate calculations near that region.

B. Interfacial stiffness

As previously stated, minimization of line tension causes the clusters to take on a circular shape. Although specific thermodynamic values can be determined as a function of $u_\epsilon$, it is useful to generalize these interfacial energies in terms of interfacial stiffness, $\tilde{\gamma}$, which is
FIG. 2. A colloidal cluster under different magnetic field strengths. (a-c) From top to bottom, optical microscopy images of a colloidal cluster formed under magnetic fields of 8.5, 9, and 11 Gauss respectively, corresponding to pair potentials with magnitudes of $5.8 k_B T$, $6.6 k_B T$, and $9.8 k_B T$ respectively, (d-f) Particle positions within the cluster for each of the three states based on their local orientation order parameter, $\psi_6$, value. $\psi_6$ ranges from 0 for low order (blue) to 1 for high order (red), (g-i) Plots of the packing density, $\eta$, and $\psi_6$ as a function of distance away from the center of mass. The shaded gray areas represent the distance from the Gibbs dividing line to the bulk values of $\eta$ of the two phases. (Scale bar=10 $\mu$m).

the sum of line tension and its second derivative with respect to the angle, $\theta$, azimuthally normal to the interface ($\tilde{\gamma} = \gamma + \frac{\partial^2 \gamma}{\partial \theta^2}$), where the second term accounts for the orientation of the interface. As shown in Fig. 2(a) the interface is isotropic at low magnetic field strengths. However, at high magnetic fields, shown in Fig. 2(c), the interface becomes anisotropic. Such is also the case for crystal-liquid interfaces [11, 21] and crystal-crystal grain boundaries [22].
Interfaces corresponding to weakly associating particles fluctuate strongly compared to particles that are strongly associating. These radial fluctuations can be analyzed using Fourier methods to find the line tension \([12, 23, 24]\). For a two-dimensional system that is discrete and finite in size, one should account for the measurement uncertainty by estimating the modes at which we reach noise level. In order to estimate the Fourier modes that are insensitive to noise, we plot the Fourier coefficients \((a_k, b_k)\) on a log-log scale as a function of the Fourier mode, \(k\), as shown in Fig.3(a). The plot has a slope of -2 showing an excellent agreement with the theoretical predictions in references \([23]\) and \([25]\). In our system, the noise level occurs at \(k\) higher than 15 to 20 modes.

As the interaction potential between the particles increases, \(\tilde{\gamma}\) increases and reaches a saturation value, as shown in Fig.3(b). Interestingly, at the lowest field strengths the standard deviation in \(\tilde{\gamma}\) is small compared to that observed with stronger interaction potentials. At low \(|u_e|\) where \(\gamma\) is the same along the interface, \(\frac{d^{2}\gamma}{d\theta^{2}}\) term becomes negligible and \(\tilde{\gamma} \approx \gamma\). For larger potential energies, however, where the cluster orientation is anisotropic and differs from one crystallite to another, \(\frac{d^{2}\gamma}{d\theta^{2}}\) becomes significant. For this reason, the variation in the interfacial stiffness increases as the clusters become more crystal-like as shown by the increasing scatter in Fig.3(b). At well depths of \(5.8k_bT, 6.6k_bT, \text{ and } 9.8k_bT\), \(\tilde{\gamma}\) is found to be \(1.6 \pm 0.55 k_bT/D, 2.5 \pm 0.66 k_bT/D, \text{ and } 3.7 \pm 1.5 k_bT/D\) respectively. Averaging measurements over sixty distinct clusters, the interfacial stiffness ranges between 1.73\(\pm\)0.15 and 3.76\(\pm\)1.54 \(k_bT/D\). These values correspond to \((6.5 \pm 0.56) \times 10^{-15}\) and \((1.4 \pm 0.58) \times 10^{-14}\) when converted to units of \(J/m\).

We compare our line tension measurements to other 2D colloidal systems\([26–29]\), which mainly involve solid interfaces, and find that the values are on \(\mathcal{O}(10^{-15} k_bT/D)\) or \(\mathcal{O}(10^{-16} − 10^{-15} J/m)\). The line tensions were slightly lower than our liquid-like clusters and at least an order of magnitude less than our crystallites. We believe our system is able to reach values greater than typical colloidal models due to the influence of long-range interaction energy caused by the particles near the interface. Molecular dynamics simulations of 6-12 Lennard-Jones (LJ) systems, on the other hand, typically show line tensions ranging from \(\mathcal{O}(10^{-12} − 10^{-10} J/m)\) \([30–32]\) which are orders of magnitude larger than our values. This is due to a number of dissimilarities between the two systems, such as length scale, entropic effects, and the type of interaction driving the phase separation \([33]\).

Since \(\gamma\) represents \(F^\sigma/l\), it is interesting to note that although we use two completely
FIG. 3. Characterization of the clusters’ interfacial fluctuation. (a) The correlation between the Fourier coefficients and the mode number reaching noise floor at $k=20$. Inset shows the same data set, but with an x-axis of $1/(k^2 - 1)$ to show that the slope is in agreement with Eq. B2 in Appendix B. (b) Interfacial stiffness values at different particle pair interactions. Blue dots are experimentally obtained measurements of interfacial stiffness. Blue highlighted area is the standard deviation of the data. Note that as $u_ε$ increases anisotropy variations increase leading to larger deviations in the interfacial stiffness.

We find different methods to calculate $F^σ/l$ (Fourier expansion of the interfacial fluctuation) and $U^σ/l$ (using the dipole model), both excess energies per unit length fall under the same order of magnitude.

Once we determine $E$ and $γ$, we can find the excess entropy per unit length using the following relationship:

$$S^σ/l = -(γ - E)/T$$  \hspace{1cm} (3)$$

We find $S^σ/l$ for each of the three states in Fig.2 to be $5.6 \ k_b/D$, $11.7 \ k_b/D$, and $18.7 \ k_b/D$ respectively. Note that the excess entropy is an estimation and becomes less accurate at high fields since the excess Helmholtz free energy per length is equal to $γ$ and not $\tilde{γ}$. More exact calculation of thermodynamic parameters, such as Helmholtz free energy, requires an accurate calculation of the spatial anisotropy of the cluster in order to obtain a better approximation for $S^σ$. 

FIG. 4. Coalescence of two clusters into a large cluster under a field frequency of 20 Hz and field strength of 10 Gauss. Scale bar=10 μm.

IV. CLUSTER COALESCENCE

Thus far we have focused on isolated quasi-stable clusters. Interesting interfacial dynamics can also be observed when clusters are near each other and begin to coalesce as shown in Fig.4. Previous experiments [34, 35] and simulations [36, 37] have been performed to capture the coalescence of a variety of nano-scale and micro-scale systems to investigate changes in morphology and the formation of topological defects [38]. Here, we follow the dynamics of the colloidal clusters as they coalesce to form larger aggregates and qualitatively show the difference between clusters when they are coalescing at low and high field strengths. The coalescence mechanism can be described in four stages. First, clusters translate towards one another resulting in a migration phase. Next, a neck of particles connects the clusters, as shown in Fig.4. The resulting neck thickens and particles at the interface rearrange to move particles with ψ closer to unity into the bulk phase while translating particles with low ψ move to the interface. Finally, the merged cluster rearranges into a larger cluster that
FIG. 5. Micrographs of clusters coalescing taken over time at three interaction potentials (a) $u_\epsilon = -5.2k_bT$ (b) $u_\epsilon = -6.6k_bT$ (c) $u_\epsilon = -9.8k_bT$. The images are color-enhanced to indicate the bond orientation order parameter of each particle, and thus the level of disorder, in each of the three cases. See SM for videos of their coalescence. Scale bar 10 µm.

is once again quasi-stable with a circular morphology. For more crystalline clusters, grain boundaries are observed along the contact line between two clusters as they merge as shown in Fig.4.

The relaxation and minimization of the potential energy of a cluster depends largely on the mobility of the constituent particles. As $|u_\epsilon|$ increases, the clusters are less mobile and therefore require more time to reach a global minimum potential energy. In Fig.5, the coalescence of colloidal clusters is displayed over time at three different interaction potentials. At low $|u_\epsilon|$, the larger cluster has a $\tilde{\gamma}$ similar to that of the two original clusters. Coalescence driven formation of topological defects is evident at higher interactions as shown
in Figs. 5(b) and 5(c), and the resulting grain boundaries can range in thickness depending on
the strength of the interaction potential. At large enough $|u_\epsilon|$, the thickness of the disorder
or grain boundary can be as small as one particle diameter [Fig. 5(c)]. These grain boundaries
then migrate toward the interface and dissipate (see SM for videos of the coalescence). The
presence of topological defects in a crystalline system slows the progress toward a minimum
free energy state [39]. The coalescence of these crystallites therefore serve as a promising
model for expanding studies that focus on the formation and migration of topological defects
[26, 40].

V. CONCLUSION

In summary, we have varied the strength of an anharmonic particle-particle interaction
potential to characterize the changing interfacial properties of various 2D colloidal clusters.
Structural parameters, such as the bond order parameter, are correlated to several ther-
modynamic quantities such as surface excess energy per unit length, surface excess entropy
per unit length, and line tension. The tunability of the anharmonic potential presented
here is ideal to study long-range attractive 2D materials. This class of collective colloidal
phenomena form the basis by which 2D interfacial dynamics can be explored.

Appendix A: Experimental Details

The colloidal particles used in this study are $1.1 \pm 0.08 \mu m$ paramagnetic carboxylated-
coated MyOne Dynabeads® (Invitrogen). A volume magnetic susceptibility of 1.4 is acquired
as result of iron oxid particles being embedded into a polystyrene matrix that makes up each
particle. The stock suspension is washed and dispersed an aqueous solution of 10 mM NaCl.
A 0.035 vol% of the suspension is injected into a glass chamber that consists of two plasma-cleaned coverslips (Ted Pella, Inc.): a 22 × 22 mm acting as a top cover, and a 24 × 40 mm as the bottom surface. After plasma cleaning the coverslips, a 50 µm thick Parafilm® wafer is placed between the edges of the coverslips. The Parafilm acts as a spacer and, upon heating, as an adhesive to bind the coverslips. The suspension of paramagnetic particles of known concentration is added to the resulting chamber. The chamber is then sealed with epoxy followed by NOA 81 (Norland Optical Adhesive®) to prevent any evaporation and capillary leakage from occurring. Since the particles have a density of 1.8 g/cm³, they will sediment to the bottom of the chamber with a slight elevation due to the particles being negatively charged, moving freely in the XY-plane. Following the formation of the colloidal clusters, optical microscopy images are captured using a QICAM Fast 1394 camera and a SimplePCI imaging software. Particle positions are determined using standard particle tracking algorithms [41].

Appendix B: Interfacial Stiffness Measurement

Fluctuations of the interface are examined using Fourier analysis to quantify the interfacial stiffness as a function of magnetic field strength. The correlation function in finite two-dimensions entails finding the radial distance of the interface from the center of mass as a function of the angle θ that is normal to the interface. The fluctuations are then represented by the Fourier coefficients [23, 25]:

\[ R(\theta) = R_0 \left[ 1 + a_0 + \sum_{k=1}^{\infty} a_k \cos(k\theta) + \sum_{k=1}^{\infty} b_k \sin(k\theta) \right] \]  

where \( R_0 \) is the equilibrium radius of the cluster and \( a_k \) and \( b_k \) are the Fourier coefficients for mode number \( k \). The interfacial stiffness is correlated with the Fourier coefficients as [23]:

\[ \langle a_k^2 \rangle + \langle b_k^2 \rangle = \frac{2k_BT}{\pi R_0 \gamma} \left( \frac{1}{k^2 - 1} \right) \]

The first twenty modes are considered as further modes are indistinguishable from the noise floor as shown in Fig.3(a).
Appendix C: Analytical approximations

The potential energy of a colloidal cluster is determined by calculating the potential energy between each particle pair using a modified dipolar model [16]. The potential energy is approximated for a given particle within the cluster by summing the particle-pair interaction energy with every particle within 10 particle diameters. The interface is determined by calculating the packing fraction, \( \eta \), of particles as a function of distance away from the cluster’s center of mass. In order to generate a spatial profile of particle density, the packing fraction is measured using annular disks in radial increments of one particle diameter. The position of the Gibbs dividing line is the location at which the integral of the density (or packing fraction) curve is equal as the spatial profile transitions from the bulk of the cluster to the dilute phase. A non-linear regression is used to model the curve and find the distance at which the value falls from 90\% to 10\% [42] representing the interfacial width, \( W_{10-90} \), [20] and taken to be the limits of the integral. The surface excess energy is the excess potential energy at the Gibbs dividing line per unit length (\( E(R_{Gibbs}) = U^s/l \)).

The local bond orientation order parameter [43], \( \psi_6 \), is used to characterize the structural order throughout each cluster:

\[
\psi_6 = \left\langle \frac{1}{N} \left| \sum_i \frac{1}{N_n(i)} \sum_{k(i)} \exp(i6\theta_{ik}) \right| \right\rangle
\]  

(C1)

where \( N \) is the total number of particles \( i \) in a radial region of interest, \( N_n(i) \) is the total number of nearest neighbors for each particle \( i \) obtained using a Voronoi diagram, and \( \theta_{ik} \) is the angle of the connecting vector between particles \( i \) and \( k \) relative to a reference line (positive \( x \) axis, in this case). The spatial profile is generated utilizing the same annulus used to calculate the packing fraction. The bond orientation order parameter quantifies the configuration in the interior domain of the cluster and follow the change in its crystallinity as the interaction energy between particles changes.
