(Dated: February 6, 2020)

We perform coherent nonlinear spectroscopy of excitons in single-layers of MoSe₂ and WSe₂ encapsulated between thin films of hexagonal boron nitride. Employing four-wave mixing microscopy we identify virtually disorder free areas, generating exciton optical response at the homogeneous limit. Focussing on such areas, we measure exciton homogeneous broadening as a function of environmental factors, namely temperature and exciton density. Exploiting FWM imaging, we find that at such locations, nonlinear absorption of the exciton excited states and their coherent couplings can be observed. Using the WSe₂ heterostructure, we infer coherence and density dynamics of the exciton 2S state. Owing to its increased radiative lifetime, at low temperatures, the dephasing of the 2S state is longer than of the 1S transition. While scanning various heterostructures across tens of micrometers, we conclude that the disorder, principally induced by strain variations, remain to be present creating spatially varying inhomogeneous broadening.

I. INTRODUCTION

The interest in two-dimensional (2D) layered semiconductors stems from novel functionalities that can be obtained by varying their thickness, down to the single-layer (SL) limit, or by stacking layers from different materials to create van der Waals heterostructures. Semiconducting transition metal dichalcogenides (TMDs) in the SL form display direct band gap¹ spanning across near infra-red and visible range. They typically show 10% absorption, which can approach unity, by engineering their photonic environment². They are thus promising for future flexible optoelectronic applications, such as: LEDs, lasers, photovoltaics, photodetectors, electroluminescence or optical modulators³.

On the more fundamental level, SL-TMDs are nowadays a benchmark to study the physics of excitons (EXs), hydrogen-like bound states formed by Coulomb interaction between an electron and a hole. In typical direct band gap bulk semiconductors such as GaAs, due to the large dielectric screening and small effective mass of the carriers, the resulting EX binding energy is barely a few millielectronvolt (meV). This is negligible compared to the thermal fluctuations, unless the sample is studied at low temperatures. In SL-TMDs though, due to large effective masses and reduced dielectric screening, the EX binding energy is increased up to several hundred meV, such that even at room temperature the optical properties are governed by EX transitions. Furthermore, their band structure displays a pair of non-equivalent valleys

as regards the spin degree of freedom, establishing original selection rules for the excitation and emission of light, where the EX valley index is locked with the light helicity.

SL-TMD have been initially fabricated as bare flakes deposited directly on SiO₂ substrates. In such configuration, they suffer from a direct contact with the environment and its invasive chemistry, thus become unstable and prone to structural aging⁴ and photodegradation⁵. Due to microscopic and macroscopic disorder factors — such as: strain, wrinkling, flake deformations and cracks, lattice defects and vacancies, variation of charge state and of dielectric constant in the substrate — the optical response was largely dominated by the inhomogeneous broadening^{6,7}, σ . Recently, it was demonstrated that surface protection by encapsulating SL-TMDs between layers of hexagonal boron nitride *h*-BN^{8–11} provides stable samples with low disorder, avoiding surface contaminations causing the EX broadening. Encapsulation thus yields step-like improvement of optical properties. The main indicator of such improvement was the narrowing of the EX linewidth and appearance of the Rydberg series of the EX's excited states^{10,12–14}.

II. EXPERIMENT

The question arises if the structural disorder in such heterostructures can be suppressed to the point, where σ is not detectable in the optical response? If so, how

Figure 1. **Schema of pulse sequences used in the experiments and resulting forms of the four-wave mixing transients** a) Exciton coherence dynamics is measured by varying τ_{12} and keeping $\tau_{23} = 0$. In a presence of inhomogeneous broadening TR-FWM is a photon echo. When homogeneous broadening dominates, FWM is a free induction decay. b) Exciton density dynamics is probed when varying τ_{23} and fixing $\tau_{12} = 0$.

can one demonstrate that the EX transition linewidth indeed attains the homogeneous limit, γ ? Another query regards the spatial extensions, on which such optimal conditions can be maintained. To address these issues one has to use an optical microscopy technique capable to separate σ and γ within the transition spectral line-shape. Four-wave mixing (FWM) spectroscopy, which is the principal tool in our work, has been conceived for this very purpose.

FWM is a nonlinear polarization in the material, proportional to $\mu^4 \mathcal{E}_1^* \mathcal{E}_2 \mathcal{E}_3$, where $\mathcal{E}_{1,2,3}$ are three short laser pulses generated by a femtosecond laser and μ is the transition oscillator strength. In this approach, σ and γ can be differentiated, by monitoring time-resolved (TR) FWM, while varying the time delay between \mathcal{E}_1 and \mathcal{E}_2 , τ_{12} . In the presence of σ , FWM appears as a photon echo¹⁵. As depicted in Fig. 1 a, TR-FWM is a Gaussian peak centered at $t = \tau_{12}$ and displaying the temporal width proportional to $1/\sigma$. Such an echo builds up due to the phase conjugation (labeled with \star) between the first order absorption created by \mathcal{E}_1 and FWM. Conversely, in the homogeneous limit, FWM transient shows the exponential decay starting at $t = 0$ for whatever τ_{12} , also drawn in Fig. 1 a. This is known as free induction decay, adopting the nomenclature used in the NMR spectroscopy. In general, (σ, γ) pair can be accurately retrieved by a two-dimensional fitting¹¹ of TR FWM for various τ_{12} .

To enable microscopy, FWM is here detected through optical heterodyning. In short, i) $\mathcal{E}_{1,2,3}$ are modulated by distinct radio frequencies $\Omega_{1,2,3}$ around 80 MHz using acousto-optic deflectors. $\mathcal{E}_{1,2,3}$ propagate co-linearly and are focussed onto the sample down to the diffraction limit using a microscope objective of NA=0.65. ii) in the detection path, the reflected signal is interfered with the reference beam \mathcal{E}_R modulated at the phase-locked linear combination of radio-frequencies $\Omega_3 + \Omega_2 - \Omega_1$, sensitive to the FWM response. iii) background-free spectral interference between \mathcal{E}_R and FWM is then recorded as DC signal on a CCD camera, which is installed at the output of the imaging spectrometer¹⁶. FWM field is obtained

via spectral interferometry, granting access to the amplitude and phase of the signal. Thus, the modeling often requires to apply complex response functions, to properly account for detection of the field and potential interference effects. This setup is particularly suited to perform FWM micro-spectroscopy with a high signal to noise ratio, accessing the EX coherence dynamics with an enhanced temporal (spatial) resolution of 150 fs (500 nm). Further details regarding the experimental technique can be found in Refs. [16 and 17], while sketches of the experimental setup are presented in supplementary material in Refs. [18 and 19].

III. RESULTS

A. Photoluminescence and FWM mapping of a MoSe₂ heterostructure

We first present results obtained on a *h*-BN/MoSe₂/*h*-BN heterostructure. Its optical image under white light illumination, is shown in Fig. 2 a. The edges of the MoSe₂ flake are contoured with the dashed line. The dark spots correspond to the air blisters between the flake and the top *h*-BN having the thickness around 20 nm. The bottom *h*-BN instead shows terraces of different thickness 232 nm (blue area), 240 nm (yellowish), 252 nm (orange) and 290 nm (red). To assess the optical response, the heterostructure is cooled down to T=5 K and we perform confocal photoluminescence (PL) under non-resonant CW excitation at 710 nm, at the position marked with a blue circle in a). As shown in Fig. 2 c, in the PL not only the neutral EX transition is observed, but also the trion (TR) one. For the latter, we note the characteristic low energy tail in the PL signal. While, owing to the residual strain, the spectral position of both transitions fluctuate across the sample by around 15 meV, the TR binding energy is constant and equal to 26 meV. In Fig. 2 d, we present the PL imaging of the sample obtained *via* raster scanning the excitation and spectrally integrated over TR and EX transitions. It is interesting to notice the correlation between the spectrally integrated PL intensity and the thickness of the bottom *h*-BN terraces: the thinner the latter, the stronger PL is observed. This result is consistent with the recent observation that the EX radiative lifetime can be tuned through the Purcell effect, when varying the thickness of the surrounding *h*-BN layers²⁰. To investigate this scenario we propose to perform time-resolved resonant spectroscopy.

To measure the resonant optical response we first perform white light reflectance restricting the signal to the spot marked with a blue circle. The result is shown in Fig. 2 b. Only EX transition appears as a dispersive quasi-Lorentzian line, with the full width at half-maximum (FWHM) of merely 2.5 meV. The trion line is absent owing to encapsulation and resonant excitation, which both suppress density of free carriers re-

quired to form charged excitons. In order to measure coherent nonlinear response FWM microscopy is carried out. In Fig. 2e we present a typical spectral interferogram between \mathcal{E}_R (brown line) and the FWM signal at $\tau_{12} = \tau_{23} = 0$. FWM image is constructed by plotting time-integrated (TI) FWM amplitude measured for different points on the sample and is shown in Fig. 2f. Although the strongest FWM is measured at the flake area covered with the “blue” h -BN stripe, globally there is no clear correlation between the FWM amplitude, reflecting to large extent the EX radiative rate, and the thickness of the encapsulating layers. This is attributed to the underlying disorder, generating σ . We have recently demonstrated¹¹ that there exists correlation between σ and the EX lifetime: the latter is increased at the areas showing larger σ due to the stronger exciton localization. The same effect is present here, as evidenced in the Supplementary Fig. S1. We also note that different interference conditions from the various thicknesses of the encapsulating layers generate different electric field distributions of the excitation laser at a plane of MoSe₂ SL. This could yield different PL intensities measured at different h -BN thicknesses in Fig. 2d.

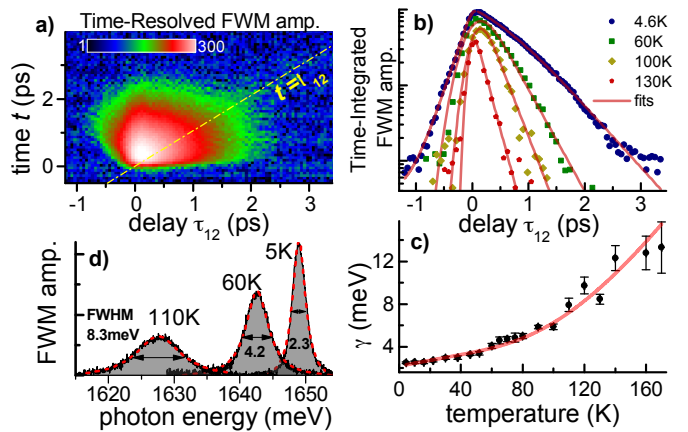

Figure 3. **Temperature dependent EX dephasing measured at the area of MoSe₂ heterostructure dominated by the homogeneous broadening.** a) Time-resolved FWM amplitude measured for various delays τ_{12} . FWM transient appears as free-induction decay indicating that the response is dominated by γ . b) Time-integrated FWM amplitudes *versus* τ_{12} presented for several temperatures along with the fits (red lines). c) Homogeneous broadening γ as a function of temperature, indicating phonon-induced dephasing mechanism, as modeled with the red line. d) Exemplary spectra of FWM amplitude for different temperatures, $\tau_{12} = 0.6$ ps.

B. Dephasing mechanisms of excitons in the MoSe₂ heterostructure

It was recently reported that FWM transient in bare SL TMDs is a photon echo^{6,7,19}. In Fig. 3a we present TR FWM for different delays τ_{12} measured at the same area as in Fig. 2b. Here, there is virtually no sign of photon echo formation; the maximum amplitude of the transient does not follow the diagonal $t = \tau_{12}$. Instead, for $\tau_{12} > 0$ FWM is maximal for $t = 0$, and then evolves as the exponential free induction decay for $t > 0$. This shows that the optical response is dominated by the homogeneous broadening, *i.e.*, $\gamma \gg \sigma$. It is worth to note that FWM is here also detected for $\tau_{12} < 0$. In such configuration, \mathcal{E}_1 arrives last and triggers FWM through the local field effect^{11,21}. Furthermore, as \mathcal{E}_1 - \mathcal{E}_R delay increases, FWM sets off for increasingly longer times when going into more negative delays, as indeed visible in the color map.

To measure γ , we plot TI FWM *versus* τ_{12} , as shown in Fig. 3b. The data are modeled by a convolution of a Gaussian, reflecting pulse duration of around 150 fs and exponential decay $\exp(-\gamma\tau_{12}/2\hbar)$, parameterized with γ (FWHM) or dephasing time $T_2 = 2\hbar/\gamma$. At low temperature $T=4.6$ K we measure $\gamma = (2.5 \pm 0.1)$ meV. This differs from around 1 meV measured in bare MoSe₂ SLs⁷ and is therein attributed to longer EX lifetime due to localization on disorder. The latter is significantly larger in bare SLs, as monitored by σ .

On top of ideal TMD crystal properties — determin-

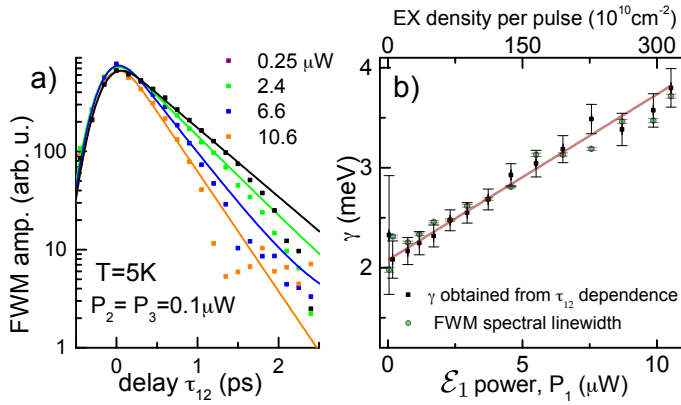

Figure 4. **EX dephasing measured as a function of the resonantly generated density at $T=5$ K at the area of MoSe_2 heterostructure entirely dominated by homogeneous broadening.** a) τ_{12} -dependence of the time-integrated FWM amplitude measured for different \mathcal{E}_1 excitation powers, P_1 . b) Homogeneous broadening γ versus EX density (black squares), compared with FWM spectral FWHM (green circles).

ing the morphology of the EX wave function, its binding energy and radiative lifetime — there are at least three major environmental parameters influencing γ : temperature, EX density and local disorder, which will be considered in the following.

In Fig. 3c we present γ measured for different temperatures. The apparent increase of γ is modeled by the sum of linear increase and exponential activation part, due to interaction with acoustic and optical phonons, respectively. The data are fitted with the following equation: $\gamma(T) = \gamma_0 + aT + b/[\exp(E_1/k_B T) - 1]$, with $E_1 = 37$ meV, corresponding to activation energy of optical phonons²². Qualitatively, the phonon dephasing mechanisms are therefore similar as in bare MoSe_2 SLs⁷. We note that temperature induced increase of the linewidth can be directly monitored in the FWM spectra, as exemplified in Fig. 3d. Owing to negligible σ , there is a very good correspondence between γ retrieved from the coherence dynamics and directly measured FWM spectral linewidth. We emphasize that such comparison to be valid, requires prior knowledge that the transition line-shape is homogeneous. Such an independent assessment is here provided by TR FWM data.

An important factor influencing γ is the EX density, n . With its increase, EX-EX interaction increases, causing excitation induced dephasing, as observed in the past in semiconductor quantum wells^{23,24} and more recently for WSe_2 ⁶ and MoS_2 ¹¹ SLs. In Fig. 4a we present exemplary curves of coherence dynamics, where a steeper slope is visible with increasing \mathcal{E}_1 intensity, P_1 . Monitoring the impinging power and assuming absorption of approximately 10%, we can estimate n . In Fig. 4b we plot the resulting $\gamma(n)$ dependence: the broadening is well visible, we observe that γ can be doubled with

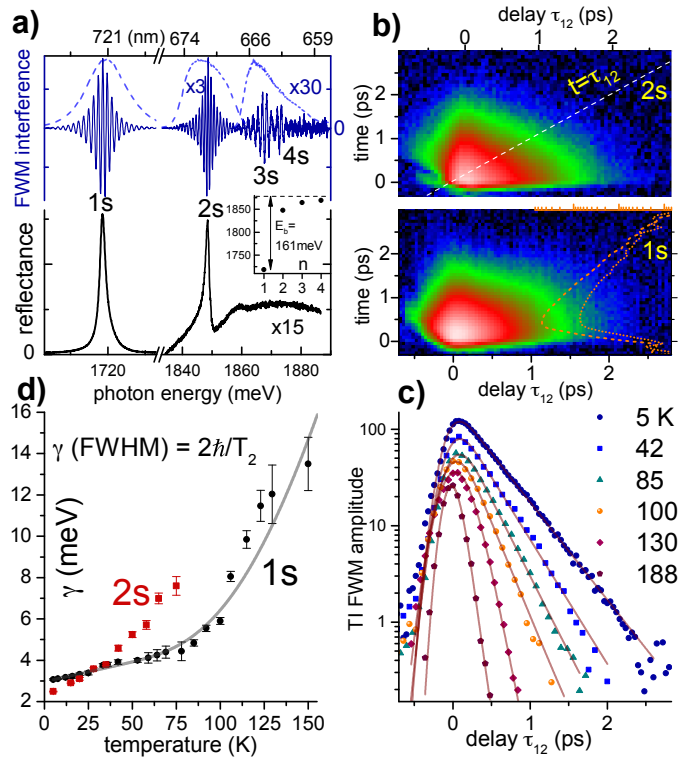

Figure 5. **Four-wave mixing microspectroscopy of the exciton transitions in a WSe_2 heterostructure.** a) Measured micro-reflectance showing linear response of 1s and 2s states (bottom) and FWM-reference spectral interference revealing exciton nS series up to $n=4$. Inset: energy versus quantum number n . b) Transients of the FWM amplitude versus τ_{12} showing free-induction decay (directly exemplified with orange traces for $\tau_{12} = 0.2$ ps and 1 ps) for 1S and 2S states. c) Time-integrated FWM amplitudes as a function of τ_{12} for temperatures as indicated. d) Temperature dependence of the homogeneous broadening γ for 1S and 2S states. The modeling is indicated with a gray trace.

300-fold increase of the resonantly generated EX density. We propose to describe the effect by the linear dependence $\gamma(n) = \gamma_0 + \alpha \times n$, where γ_0 is the zero-density linewidth and α is the interaction parameter, both established for $T=5$ K. From the linear fit, we obtain $\gamma_0 = (2.07 \pm 0.03)$ meV and $\alpha = (5.4 \pm 0.2) \times 10^{-13}$ meV cm^2 . The interaction strength is here 5 times smaller compared to similar studies performed on WSe_2 SLs⁶. In Fig. 4b we also show that the broadening is directly visible in the FWM spectra and in a good agreement with the coherence dynamics measurements.

C. Reflectance and FWM response in a WSe_2 heterostructure

The second part of this work is devoted to investigations of a WSe_2 heterostructure. Its optical image is presented in Fig. 8a. A large WSe_2 SL of around (60 \times

60) μm was transferred at the bottom $h\text{-BN}$ (90 ± 10) nm thick layer and then partially covered with the top one of nominally the same thickness, resulting in the elongated heterostructure, with a shape marked with a dashed contour in Fig. 8 a. Let us first investigate the area of the flake marked with a cross, which is free from wrinkling (occurring at the edges) and air blisters (visible as dark spots on the neighboring surface).

The reflectance spectrum measured at $T=5\text{K}$ is presented in Fig. 5 a. The fundamental EX 1S transition is detected as an emissive quasi-Lorentzian line, with FWHM only 2.6 meV. Interestingly, the second resonance is clearly observed around 130 meV above EX 1S, with even a sharper line-shape of 1.7 meV (FWHM). It is attributed to the EX excited 2S state. An additional spectral wiggle is seen another 10 meV higher, however its contrast is not sufficient for the unequivocal assignment of the underlying transitions. FWM spectral interferograms at $\tau_{12} = 0$ are shown as blue traces in Fig. 5 a. To drive FWM of the 1S EX we still employ a Ti:Shapphire laser. However, to study the excited states occurring well below 700 nm, an Optical Parametric Oscillator must be used. As the technique is background free and detection is at the shot-noise limit, apart from 1S and 2S states, FWM reveals further resonances attributed to 3S and 4S states. When plotting the energy versus the quantum number (see inset) we observe non-hydrogenic series, in line with previous findings¹² and the EX binding energy^{13,14} of $E_b=161\text{meV}$.

D. Exciton coherence dynamics in the WSe_2 heterostructure: dephasing and coherent coupling

FWM transients *versus* τ_{12} measured for 1S and 2S states are shown as color maps in Fig. 5 b. With increasing τ_{12} , FWM is emitted as an exponentially decaying transient with a maximum centered around $t = 0$. We see strictly no indication of the photon echo formation. FWM takes the form of the free induction decay, proving that at the probed position, the EX transition is homogeneously broadened. To determine FWHM of $\gamma = 2\hbar/T_2$, in Fig. 5 c we plot time-integrated FWM amplitude as a function of τ_{12} . Resulting coherence dynamics displays a mono-exponential decay over three (six) orders of magnitude in a FWM field (intensity). From these decays we extract γ , similarly as for the MoSe_2 heterostructure (Fig. 3 b).

Let us note that the excitation bandwidth of the OPO laser is sufficient to simultaneously cover the excited states 2S, 3S and 4S, as shown in Fig. 6 a. Because these transitions share the same ground state, they are expected to be coherently coupled (absorption on one of the transitions, mutually generates FWM on the other ones). Such coupling should therefore induce quantum beating in the corresponding coherence dynamics. In Fig. 6 b, we present such dynamics measured *via* τ_{12} -dependence. Indeed, we observe that FWM is here modulated with the

Figure 6. **Coherent coupling in the EX excited states measured in the WSe_2 heterostructure.** a) FWM spectral interferogram showing EX excited states 2S, 3S and 4S (black), simultaneously excited by the OPO laser pulse (brown). b) The beating measured in the coherence dynamics *via* TI FWM(τ_{12}) indicates the presence of coherent coupling between the excited states, especially between 2S and 3S, which dominate the spectrum.

period of $\Delta = 2\pi\hbar/\delta = 0.26\text{meV}$, well corresponding to the 2S-3S splitting $\delta \simeq 16\text{meV}$. We can resolve two oscillation periods within the initial $0 < \tau_{12} < 0.5\text{ps}$. For subsequent delays $\tau_{12} > 0.5\text{ps}$ the beating is smeared out owing to fast dephasing of higher excited states. This measurement thus indicates that one can induce couplings within the Rydberg states of TMD EXs.

Focussing back on the dephasing mechanisms, in Fig. 5 c we observe that for increasing temperature, the FWM decay gets more pronounced, owing to the increase of γ (and correspondingly, shortening of dephasing time T_2). Such temperature dependence of γ , measured at 1S and 2S states²⁵ is summarized in Fig. 5 d.

The exciton 1S EX transition is once again modeled with a linear increase, with $\gamma_0 = (2.96 \pm 0.05)\text{meV}$ and $a = (0.02 \pm 0.002)\text{meV/K}$, attributed to the interaction with acoustic phonons, and the exponential activation term with $E_1 = 44\text{meV}$, due to the onset of interaction with optical phonons²².

As regards the 2S EX transition, let us remind that for an ideal two-dimensional Wannier exciton, the oscillator strength μ scales with the quantum number n as: $\mu \propto (n - 1/2)^{-3}$. The radiatively limited broadening of the 2S EX could be therefore estimated to be $3^3 = 27$ times weaker than the one of the 1S EX, thus only around 0.1 meV at low temperature. It is interesting to note that for $T < 20\text{K}$, we indeed measure $\gamma(2S) < \gamma(1S)$. However $\gamma(2S)$ is around 20 times larger than the radiative limit, indicating that even low temperature dephasing is dominated by a non-radiative decay, plausibly through the scattering into 1S EX at high center-of-mass in-plane momenta. With increasing temperature, we observe much stronger EX dephasing for the 2S state with respect to 1S. However, recent theoretical work²⁶ predicts that 2S transition is less prone to interaction with phonons than the 1S. We here therefore refrain from the modeling of the $\gamma(T)$ dependence measured for the 2S EX.

E. Population dynamics of 1S and 2S excitons

To further elucidate the interplay between radiative and non-radiative decay mechanisms of EX 1S and 2S transitions, we infer the dynamics of resonantly excited EX density. We set $\tau_{12} = 0$ and employ \mathcal{E}_1 and \mathcal{E}_2 to drive modulation of EX's population, slowly varying with the frequency $\Omega_2 - \Omega_1 = 1$ MHz. TI-FWM, triggered *via* \mathcal{E}_3 delayed from \mathcal{E}_2 by τ_{23} , reflects the amplitude of this oscillating EX density, as depicted in Fig. 1 b. Exemplary data reflecting such dynamics of 1S EX measured at $T=5$ K for increasing P_1 and fixed P_2 and P_3 are given in Fig. 7 a. While the EX coherence, inspected in previous sections, vanishes after a few ps, the EX density evolves here on a timescale of at least one nanosecond. This is consistent with recent FWM experiments on SL MoSe₂²⁷ and MoS₂ heterostructure¹¹, and also perovskite nanocrystals²⁸ and nanoplatlets²⁹.

Qualitatively, in the dynamics we distinguish: i) the rise from negative τ_{23} , owing to the finite duration of the laser pulses, ii) initial decay on a few hundred fs scale, attributed to the radiative decay and EX scattering to dark EX states. iii) followed after $\tau_{23} > 1$ ps by a much longer FWM decay, due to populating the dark EX states and their subsequent relaxation and interaction with the bright ones, *i.e.*, EXs within the light cone, obeying spin selection rules for radiative recombination.

Because the density dynamics is here measured *via* the interference with \mathcal{E}_R , which is phase-sensitive, it should be described with a complex response function R . The latter is here proposed in a form of a coherent superposition of three exponential decay components^{11,27}:

$$R(\tau_{23}) = \sum_{j=1}^3 A_j \Theta(\tau_{23}) \exp(i\phi_j - \tau_{23}/\tau_j) \quad (1)$$

where (A_j, ϕ_j, τ_j) with $j = (1, 2, 3)$ are amplitude, phase and decay constant of each of the three processes. The pulse width is taken into account by convoluting R with the Gaussian of $\tau_0 = 150$ fs. Furthermore, owing to the repetition period $T_R \simeq 13$ ns, there is a pile-up effect building up throughout many repetitions of the heterodyne experiment equal to $(\exp(\frac{T_R}{\tau_j}) - 1)^{-1}$. The response function therefore takes the following form: $R(\tau_{23}) = \sum_{j=1}^3 A_j \{ [\exp(\frac{T_R}{\tau_j}) - 1]^{-1} + \frac{1}{2} [(1 + \operatorname{erf}(\frac{\tau_{23}}{\tau_0} - \frac{\tau_0}{2\tau_j}))] \} \times \exp(i\phi_j - \frac{\tau_{23}}{\tau_j} + \frac{\tau_0}{4\tau_j^2})$. Finally, to fit the FWM amplitude we take absolute value of $R(\tau_{23})$.

The result of the modeling is given by red traces and retrieved set of decay constants for different P_1 is given in Fig. 7 c. For the initial decay we consistently find $\tau_1 = T_1(1S) \simeq 0.18$ ps. The second and third process decay on a scale of a few tens and a few hundred ps, respectively. They describe EX evolution in the dark state reservoirs, namely EXs with the in-plane momentum out of the light cone and the spin-forbidden ones. Note that the wiggling observed around $\tau_{23} = 100$ ps,

Figure 7. **Time-integrated FWM as a function of delay τ_{23} reflecting resonantly excited EX density dynamics in the WSe₂ heterostructure** a) Density dynamics of EX 1S measured for different \mathcal{E}_1 excitation powers, as indicated. Modeling is given with red traces. b) as in a), but measured for EX 2S. Longer radiative decay of the 2S state with respect to the 1S has its impact on the initial population loss, which is measured to be more than four times longer for the 2S state. Both measurements were performed at the same location of the flake. c) Decay constant τ_1 , τ_2 and τ_3 retrieved from the modeling of 1S EX density (a) and 2S EX density dynamics (b). d) Amplitude ratios A_2/A_1 and A_3/A_1 versus P_1 obtained from the modeling.

building up when increasing P_1 , is due to interference between all three processes. The interference becomes more pronounced as the ratios A_2/A_1 and A_3/A_1 increase with P_1 , as reported in Fig. 6 d. In other words, increasing the excitation results in higher occupancy of dark EX states and their enhanced interaction with the bright EX, which is probed with FWM τ_{23} -dependence.

In Fig. 7 b we present the density dynamics measured on the 2S EX transition. The modeling includes now only two decay processes. Interestingly the initial decay of $\tau_1 = T_1(2S) \simeq 0.75$ ps is measured to be more than four times longer than for the 1S EX, indicating longer radiative decay of the 2S state. It is however still far off from the prediction based on the relative oscillator strength, again indicating dominance of the non-radiative decay processes of the 2S states. We note that dephasing of the higher states is much faster than our temporal resolution of 150 fs, showing prominently non-radiative decay of the higher excited EX states.

F. FWM mapping of exciton 1S and 2S transitions in the WSe₂ heterostructure

An important conclusion emerging from our experiments is that EX's excited states can be observed uniquely at the areas with eradicated disorder, where the optical response is dominated by γ . To substantiate this claim, we perform FWM spatial imaging across the flake. In Fig. 8 b we present a color map where FWM amplitude and transition energy of 1S EX are encoded as brightness and hue level, respectively. Even though locally (on the areas up to $(5 \times 5) \mu\text{m}^2$) the transition energy can be quasi-constant (spectrally fluctuating an order of magnitude less than γ), globally the EX energy changes by around 25 meV. This variation is attributed to residual strain generated during the processing of the heterostructure - other sources of disorder, like variation of dielectric permittivity or doping were shown to be suppressed³⁰ in *h*-BN encapsulated TMD SLs.

To illustrate the interplay between strain-induced disorder and coherent response, we perform mapping of the EX coherence dynamics: we therefore spatially scan within the part of the heterostructure enclosed by a white square, while at each position the delay τ_{12} is varied. In Fig. 8 c we provide four examples of the time- and τ_{12} -resolved FWM. In the first pair of panels, the response clearly displays the photon echo. When cross-correlating with b), one assigns these to the areas exhibiting a strong radial strain gradient of the EX energy, generating σ . Conversely, the second pair of panels, measured on a spot showing a quasi-constant energy level, yields FWM as a free-induction decay signal. We note that at some positions, we observe FWM temporal response generated by a mixture of inhomogeneous contributions. In other words, even within the sub- μm excitation area, several domains characterized by different γ and σ can contribute to the signal, rendering quantitative analysis of these transients challenging.

Finally, we have carried out FWM spatial imaging of the 2S EX transition. As in panel b), we encode the amplitude and transition energy as brightness and hue, and present the result in Fig. 8 d. One can notice that at areas with suppressed disorder — here identified by FWM displaying free-induction decay instead of photon echo — the 2S EX transition can be observed. Interestingly, FWM of the 2S EX is suppressed at the areas exhibiting a pronounced photon echo. This indicates that absorption of EX's excited states can only be induced at locations with low disorder on both microscopic and macroscopic scales.

IV. CONCLUSIONS

We investigated coherent non-linear response of the EX transitions in high quality *h*-BN/MoSe₂/*h*-BN and *h*-BN/WSe₂/*h*-BN heterostructures. Using FWM microscopy and imaging we showed that encapsulating SLs

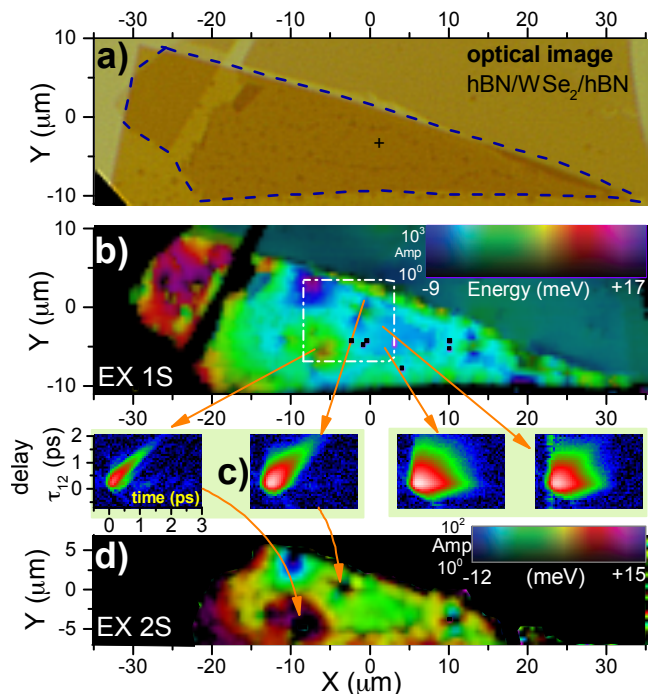

Figure 8. **Four-wave mixing imaging of 1S and 2S EXs in the WSe₂ heterostructure.** a) Optical image of the sample. The heterostructure area is enclosed with a dashed line. b) FWM imaging of the 1S EX, $\tau_{12} = 0.1$ ps. Amplitude and transition energy (with respect to central energy of 1720 meV) are encoded as brightness and hue level, as indicated. Note that WSe₂ not covered with the *h*-BN also generates FWM signal. c) Exemplary time-resolved FWM versus τ_{12} . The areas displaying strong energy gradients, owing to varying strain, generate photon echo. Free induction decay is measured on the locations where the transition energy is quasi-constant. d) FWM imaging of the 2S EX, $\tau_{12} = 0.1$ ps. Scale as in b), central energy is 1845 meV.

of MoSe₂ and WSe₂ generally provides low disorder samples, which on areas reaching $(5 \times 5) \mu\text{m}^2$ host homogeneously broadened EX transitions. At such locations, we: i) investigated EX dephasing mechanisms, ii) revealed coherent nonlinear response of EX excited states up to 4S, iii) provided indication of coherent coupling within excited states. We compared population lifetimes of 1S and 2S states, notably finding longer dephasing time (smaller homogeneous broadening) of the 2S state. This is assigned to its larger spatial extent and correspondingly longer radiative lifetime with respect to the EX 1S, as indicated by investigation of the EX population dynamics. Even though locally optical response of these TMD heterostructures is nowadays brought close to perfection, our work shows that further efforts in processing are necessary, to attain such performance across the entire heterostructure. Eliminating spatially varying disorder would, for instance, permit to quantitatively evaluate the impact of dielectric surrounding on the coherent response of TMD EXs. Furthermore, the resulting weak EX local-

ization would enable to investigate propagative aspects of EX coherence and density (diffusion) by implementing FWM with a spatially separated excitation beams.

V. METHODS: SAMPLE FABRICATION

The heterostructures were obtained by a bottom-up method using the gel-film assisted exfoliation technique. As a substrate an ultra-flat silicon wafers were used, provided by Ted Pella. The WSe_2 and MoSe_2 crystals were bought from HQ Graphene and the high purity h -BN was prepared in NIST (Japan). A bottom layer of h -BN was exfoliated directly to the silicon substrate. The flakes of required thickness were identified using the optical microscope and some of them verified using AFM. For the heterostructures h -BN/ WSe_2 / h -BN the thickness of bottom h -BN is (90 ± 10) nm. The heterostructures h -BN/ MoSe_2 / h -BN possess sequence of different thicknesses in the range from 200 to 250 nm for the bottom h -BN. SLs of TMDs and top h -BN were transferred directly from gel-film using all-dry transfer method. Heterostruc-

tures were annealed before each transfer (180°C , 5 min) to remove as much residues as possible. After completing the stacking process all samples were annealed for another 5 hours at 200°C . All heterostructures contain some air trapped between TMD and top h -BN flake (easily visible in form of bubbles in Fig. 2 a and Fig. 8 a).

VI. ACKNOWLEDGMENTS

JK acknowledges support by the European Research Council (ERC) Starting Grant PICSEN (grant no. 306387) and he is grateful for discussions with D. Wigger, M. Richter, M. Selig and J. Renard and W. Langbein. LZ acknowledges the support from the Student Project IGAPrF2019031 of Palacký.
